Elsevier | ExpertConsult.com

Enhanced eBooks for medical professionals

Compatible with PC, Mac®, most mobile devices, and eReaders, Expert Consult allows you to browse, search, and interact with this title – online *and* offline. Redeem your PIN at expertconsult.com today!

Continuously updated with the **results of late-breaking clinical trials, reviews of important new research publications, and updates on clinical practice**, masterfully selected and edited by **Dr. Eugene Braunwald**.

PIN REDEMPTION INSTRUCTIONS

Start using these innovative features today:

- Seamless, real-time integration between devices
- Straightforward navigation and search
- Notes and highlights sharing with other users through social media
- Enhanced Images with annotations, labels, and hot spots for zooming on specific details *
- Live streaming video and animations *
- Self-assessment tools such as questions embedded within the text and multiple-format quizzes *

** some features vary by title*

1. Login or Sign Up at ExpertConsult.com
2. Scratch off your PIN code below
3. Enter PIN into the "Redeem a Book Code" box
4. Click "Redeem"
5. Go to "My Library"

Use of the current edition of the electronic version of this book (eBook) is subject to the terms of the nontransferable, limited license granted on ExpertConsult.com. Access to the eBook is limited to the first individual who redeems the PIN, located on the inside cover of this book, at ExpertConsult.com and may not be transferred to another party by resale, lending, or other means.

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

CONTRIBUTORS

Jalil Afnan, MD, MRCS

Radiologist
Department of Radiology
Lahey Clinic Hospital and Medical Center
Burlington, Massachusetts
Assistant Professor of Radiology
Tufts University
School of Medicine
Boston, Massachusetts

Jeffrey A. Alexander, MD

Associate Professor of Medicine
Mayo Clinic School of Medicine
Rochester, Minnesota

Lauren F. Alexander, MD

Assistant Professor of Abdominal Imaging
Department of Radiology and Imaging Sciences
Emory University
Atlanta, Georgia

Surabhi Bajpai, MBBS, DMRD

Research Fellow
Department of Radiology
Division of Abdominal Imaging and Intervention
Massachusetts General Hospital
Boston, Massachusetts

Mark E. Baker, MD

Professor of Radiology
Cleveland Clinic Lerner College of Medicine
Case Western Reserve University
Imaging Institute
Cleveland Clinic
Staff Radiologist
Imaging Institute, Digestive Disease Institute, Cancer Institute
Cleveland Clinic
Cleveland, Ohio

Stephen R. Baker, MD, MPHIL

Professor and Chairman
Department of Radiology
Rutgers New Jersey Medical School
Chief
Department of Radiology
The University Hospital
Newark, New Jersey

Aparna Balachandran, MD

Associate Professor
Diagnostic Imaging
The University of Texas MD Anderson Cancer Center
Houston, Texas

Dennis M. Balfe, MD

Professor of Radiology
Washington University School of Medicine
St. Louis, Missouri

Emil J. Balthazar, MD

Professor Emeritus
Department of Radiology
New York University School of Medicine
Attending Consultant
Department of Radiology
Bellevue Hospital
New York, New York

Stuart A. Barnard, MA, MB, BS, MRCS, FRCR

Radiologist
Department of Radiology
Middlemore Hospital
Counties Manukau Health
Auckland, New Zealand

Ahmed Ba-Ssalamah, MD

Medical University of Vienna
Department of Biomedical Imaging and Image-Guided
Therapy
Vienna, Austria

Genevieve L. Bennett, MD

Assistant Professor of Radiology
Department of Radiology
Division of Abdominal Imaging
New York University School of Medicine
Assistant Professor of Radiology
Department of Radiology
Division of Abdominal Imaging
New York University Langone Medical Center
New York, New York

Senta Berggruen, MD

Department of Radiology
Northwestern Memorial Hospital
Chicago, Illinois

Jonathan W. Berlin, MD

Clinical Professor of Radiology
Department of Diagnostic Radiology
NorthShore University HealthSystem
Evanston, Illinois

George S. Bissett III, MD

Professor of Radiology and Pediatrics
Vice-Chairman
Department of Radiology
Duke University School of Medicine
Durham, North Carolina

Roi M. Bittane, MD

Radiology Resident
Department of Radiology
Winthrop University Hospital
Mineola, New York

Michael A. Blake, MB, MRCPI, FRCR, FFR(RCSI)

Associate Professor of Radiology
Harvard Medical School
Fellowship Director
Division of Abdominal Imaging
Massachusetts General Hospital
Boston, Massachusetts

Peyman Borghei, MD

Clinical Assistant Professor of Radiology
University of California at Irvine
Chief of Interventional Radiology
VA Hospital
Long Beach, California

Kevin P. Boyd, DO

Assistant Professor of Radiology
Children's Hospital of Wisconsin
Medical College of Wisconsin
Milwaukee, Wisconsin

Warren M. Brandwein, MD

Fellow
Body and Musculoskeletal Imaging Section
Department of Radiology
Northwestern University
Chicago, Illinois

David H. Bruining, MD

Associate Professor of Medicine
Mayo Clinic
Rochester, Minnesota

James L. Buck, MD

Professor
Department of Diagnostic Radiology
University of Kentucky College of Medicine
Lexington, Kentucky

Carina L. Butler, MD

Assistant Professor
Department of Diagnostic Radiology
University of Kentucky College of Medicine
University of Kentucky Chandler Medical Center
Lexington, Kentucky

Selim R. Butros, MD

Fellow in Abdominal Imaging and Interventional
Radiology
Department of Radiology
Massachusetts General Hospital
Boston, Massachusetts

Laura R. Carucci, MD

Professor of Radiology
Director of Computed Tomography and Magnetic Resonance
Imaging
Abdominal Imaging Section
Department of Radiology
Virginia Commonwealth University Medical Center
Richmond, Virginia

Wei-Chou Chang, MD

Department of Radiology
University of California
San Francisco, California

Raj R. Chinnappan, MD

Clinical Assistant
Abdominal and Interventional Radiology
Harvard Medical School
Massachusetts General Hospital
Boston, Massachusetts

Byung Ihn Choi, MD

Professor of Radiology
Department of Radiology
Seoul National University College of Medicine
Seoul National University Hospital
Seoul, Republic of Korea

**Peter L. Cooperberg, OBC, MDCM, FRCP(C),
FACR, FFR(RCSI)hon**

Professor Emeritus of Radiology
University of British Columbia
Vancouver, British Columbia, Canada

Abraham H. Dachman, MD

Professor of Radiology
Director, Fellowship Programs
Department of Radiology
The University of Chicago Medical Center
Chicago, Illinois

Alexander Ding, MD, MS

Department of Radiology
Division of Abdominal Imaging and Intervention
Harvard Medical School
Massachusetts General Hospital
Boston, Massachusetts

Carolyn K. Donaldson, MD, RPVI

Assistant Professor of Radiology
University of Chicago
NorthShore University HealthSystem
Evanston, Illinois

Ronald L. Eisenberg, MD, JD

Professor
Department of Radiology
Harvard Medical School
Radiologist
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Sukru Mehmet Erturk, MD, PhD

Associate Professor of Radiology
Attending Radiologist
Administrative Director
Sisli Etfal Training and Research Hospital
Department of Radiology
Istanbul, Turkey

Thomas A. Farrell, MB, FRCR, MBA

Section Head, Interventional Radiology
NorthShore University Health System
Clinical Assistant Professor
University of Chicago Pritzker School of Medicine
Chicago, Illinois

Kate A. Feinstein, MD, FACR

Professor of Radiology and Surgery
Department of Radiology
University of Chicago Pritzker School of Medicine
Chicago, Illinois

Sandra K. Fernbach, MD

Professor of Radiology (Retired)
University of Chicago Pritzker School of Medicine
Chicago, Illinois

Hector Ferral, MD

Senior Clinical Educator
Department of Radiology
Section of Interventional Radiology
NorthShore University HealthSystem
Evanston, Illinois

Florian J. Fintelmann, MD, FRCPC

Clinical Assistant in Radiology
Department of Radiology
Massachusetts General Hospital
Boston, Massachusetts

Elliot K. Fishman, MD, FACR

Professor of Radiology
Departments of Oncology and Surgery
Johns Hopkins Hospital
Baltimore, Maryland

Joel G. Fletcher, MD

Professor of Radiology
Mayo Clinic
Rochester, Minnesota

Kathryn J. Fowler, MD

Assistant Professor
Director of Body Magnetic Resonance Imaging
Department of Radiology
Washington University
St. Louis, Missouri

Aletta A. Frazier, MD

Department of Diagnostic Radiology and Nuclear
Medicine
University of Maryland School of Medicine
Baltimore, Maryland

Ann S. Fulcher, MD

Professor and Chairman
Department of Radiology
Virginia Commonwealth University Medical Center
Richmond, Virginia

Helena Gabriel, MD

Associate Professor of Radiology
Department of Radiology
Northwestern University
Chicago, Illinois

Ana Maria Gaca, MD

Clinical Associate
Department of Radiology
Duke University Medical Center
Durham, North Carolina

Kirema Garcia-Reyes, MD

Department of Radiology
Duke University Medical Center
Durham, North Carolina

Gabriela Gayer, MD

Clinical Professor
Department of Radiology
Stanford Medical Center
Stanford, California
Department of Nuclear Medicine
Sheba Medical Center
Ramat Gan, Israel

Gary G. Ghahremani, MD, FACR

Clinical Professor of Radiology
University of California Medical Center
San Diego, California
Emeritus Professor of Radiology
Northwestern University
Chicago, Illinois

Seth N. Glick, MD

Clinical Professor of Radiology
University of Pennsylvania
Penn Presbyterian Medical Imaging
Philadelphia, Pennsylvania

Margaret D. Gore, MD

Clinical Assistant Professor of Radiology
Department of Diagnostic Radiology
NorthShore University HealthSystem
Evanston, Illinois

Richard M. Gore, MD

Chief of Gastrointestinal Radiology
NorthShore University HealthSystem
Evanston, Illinois
Professor of Radiology
Pritzker School of Medicine at the University of Chicago
Chicago, Illinois

Sofia Gourtsoyianni, MD, PhD

Consultant Radiologist
Guy's and St Thomas' National Health Service
Foundation Trust
London, United Kingdom

Nicholas C. Gourtsoyiannis, MD

Professor
Department of Radiology
University of Crete Medical School
Chairman
Department of Radiology
University Hospital of Heraklion
Heraklion, Crete, Greece

Jared R. Green, MD

Assistant Professor
Department of Medical Imaging
Ann & Robert H. Lurie Children's Hospital of Chicago
Chicago, Illinois

Gianfranco Gualdi, MD

Professor of Radiology
Director of DEA Radiology Department
Sapienza University
Rome, Italy

Rajan T. Gupta, MD

Assistant Professor of Radiology
Director of the Abdominal Imaging Fellowship Program
Department of Radiology
Duke University Medical Center
Durham, North Carolina

Ravi Guttikonda, MD

Body Imaging Fellow
Northwestern Memorial Hospital
Hudson, Ohio

Robert A. Halvorsen, MD

Professor of Radiology
Medical College of Virginia Hospitals
Virginia Commonwealth University
Richmond, Virginia

Nancy A. Hammond, MD

Associate Professor of Radiology
Director of the School of Ultrasound
Northwestern University
Chicago, Illinois

Mukesh G. Harisinghani, MD

Professor of Radiology
Harvard Medical School
Massachusetts General Hospital
Boston, Massachusetts

Sandeep S. Hedgire, MD

Division of Abdominal Imaging and Intervention
Massachusetts General Hospital
Boston, Massachusetts

Frederick L. Hoff, MD

Associate Professor
Department of Radiology
Northwestern University Feinberg School of Medicine
Chicago, Illinois

Caroline L. Hollingsworth, MD, MPH

Assistant Professor
Department of Radiology
Division of Pediatric Radiology
Duke University School of Medicine
Durham, North Carolina

Karen M. Horton, MD

Professor

Professor
Department of Radiology
Northwestern University Feinberg School of Medicine
Medical Director of Computed Tomography Imaging
Department of Radiology
Northwestern Memorial Hospital
Chicago, Illinois

Benjamin M. Yeh, MD

Professor of Radiology
Radiology and Biomedical Imaging
University of California
San Francisco, California

PREFACE

In the 20 years since the publication of the first edition of *Textbook of Gastrointestinal Radiology*, much has changed in our discipline. Technologic advances have dramatically improved the capabilities of computed tomography (CT), magnetic resonance imaging (MRI), ultrasonography, fluoroscopy, angiography, and interventional radiology for abdominal and pelvic imaging and therapy. The extraordinary anatomic resolution achieved with modern imaging techniques has been complemented by the introduction and maturation of metabolic, functional, and molecular imaging, which provide new opportunities for staging and follow-up and monitoring tumor response to therapy in the oncology patient.

To keep pace with these amazing technologic, imaging, and therapeutic advances, every chapter of the fourth edition has been updated and revised. Several new chapters on molecular and functional imaging have also been included. Moreover, new authors have been recruited for nearly one third of the chapters to provide these chapters with fresh insight and perspective.

In this new edition, we have taken great care to maintain the objective of the first three editions—namely, to provide complete and up-to-date coverage on the state of the art of gastrointestinal radiology in a practical and usable form.

As in the first three editions, our basic organizing principle is the integration of rapidly changing information, common sense, and good judgment for the development of a rational and useful approach for radiologic diagnosis and treatment. To this end, the text contains sections on general radiologic principles

for evaluating the hollow viscera and solid organs and for performing and applying specific imaging and therapeutic techniques. Other sections present the clinical, radiologic, and pathologic aspects of disease in the various gastrointestinal organs. The chapters in these sections are designed to illustrate and integrate the spectrum of abnormalities seen with all diagnostic modalities available to the radiologist, including conventional radiography, barium studies, cholangiography, multidetector CT (MDCT), ultrasonography, MRI, positron emission tomography/computed tomography (PET/CT), positron emission tomography/magnetic resonance (PET/MR), angiography, diffusion-weighted MRI, and CT and MR perfusion imaging.

Once again, we have been able to assemble an outstanding group of internationally recognized authors for the fourth edition. Their time, effort, and expertise are truly appreciated. As editors, we have tried to strike a balance between uniformity of style and author individuality so that each contributor is able to speak in his or her own unique voice.

We trust that the collective efforts of the authors of the 127 chapters in this text, as well as our own, have enabled us to accomplish our goal of providing students and practitioners of gastrointestinal radiology a valuable educational resource that is clear, interesting, and enjoyable to read.

Mixed Action Agents

Drugs Affecting the Biliary Tract and Pancreas

Only a basic introduction and overview about contrast agent use in medical imaging are presented in this introductory chapter. These agents can be subdivided into intravascular contrast agents for computed tomography (CT) and angiography, intraluminal gastrointestinal (GI) tract agents, cholangiographic agents and a unique group of agents useful in magnetic resonance imaging (MRI). The currently active research field of contrast agent–assisted, image-guided therapy will be discussed briefly. In addition, there is a section on pharmacologic agents useful in GI radiology.

Intravascular Contrast Agents

IODINATED WATER-SOLUBLE AGENTS

Basic Properties

With the exception of MRI, all current intravascular contrast agents use iodine for x-ray absorption. Theoretically, sodium iodide is ideal, but its toxicity and iodism preclude its use. The complex delivery molecules developed over the years represent

an attempt to deliver the greatest iodine concentration with the least toxicity. From a simplistic viewpoint, the intravascular contrast agents can be viewed merely as vehicles for delivering iodine to a blood vessel or structure. These water-soluble intravascular contrast agents can be subdivided into the following categories: (1) ionic, high osmolality, roughly five times the osmolality of blood; (2) nonionic, low osmolality, roughly twice or slightly more than the osmolality of blood; and (3) isotonic agents—nonionic dimers. The basic structures and physicochemical characteristics of available contrast agents are not covered here; these topics are discussed in appropriate specialized publications.¹

At the x-ray energies used in CT, the mass attenuation coefficient for iodine is considerably greater than that of surrounding soft tissues and blood. After the intravascular injection of iodinated contrast, initial CT images reveal aortic and major arterial enhancement, followed by a capillary or parenchymal “blush” and eventual venous opacification. The rate of contrast injection and timing of subsequent CT scans determine the structures enhanced on any one image. Compared with earlier scanners, multidetector CT (MDCT) scanners require shorter injection rates because of the short scanning times; as a result, faster injection rates of more concentrated contrast agents are necessary, and a contrast’s viscosity has a dominant role. Various techniques of intravascular contrast agent administration are discussed elsewhere in this text.

A number of drugs, especially more acidic ones, are incompatible to mixing with contrast agents, an incompatibility less evident with nonionic agents. Nevertheless, as a general safety precaution, a drug probably should not be mixed with a contrast agent, and a catheter should be flushed if used for both drug and contrast injection.

Ionic Agents

Acetylation of aminotriiodobenzoic acid and further structural changes led to the development of ionic contrast agents. These agents are formulated as salts and consist of a cation and anion. Two commonly used cations are sodium and meglumine. The anion portion of the molecule consists of a benzene ring containing iodine substituted at positions 2, 4, and 6, plus a number of other side chains. These side chains determine water solubility and indirectly affect resultant toxicity. The benzene ring can be viewed as a scaffold for attaching iodine and side chains. When the molecule dissociates, three iodine atoms are available for every two particles in solution, or a ratio of 1.5:1.

Further refinements of ionic contrast media consist of the attachment of two monomer triiodinated benzene rings at one of the side groups. Such a dimer, containing two benzene rings, with each having three iodine atoms and only one cation particle, has six iodine atoms per two particles, or a ratio of 3:1.

Ionic contrast agents are hypertonic at the concentrations used for vascular opacification; considerable effort has been spent in an attempt to decrease their osmolality. In general, the viscosity of a sodium salt is less than that of a corresponding meglumine salt, but the sodium salt tends to be more toxic. Toxicity and viscosity limitations during intra-arterial injections are not as relevant for the intravenous (IV) injections used with CT.

Nonionic Agents

If the carboxyl group in position 1 on the benzene ring is replaced with a stable side group, the molecule no longer dissociates when in solution, and each particle in solution has three iodine atoms, or a ratio of 3:1. A dimer structure can also be achieved by linking two triiodobenzoic acid molecules (ioxaglic acid), formulated as a meglumine sodium salt, another contrast agent with a ratio of 3:1. A contrast agent with a ratio of 6:1 has also been developed (iodixanol) and is often referred to as being iso-osmolar.

Various manufacturers have taken different approaches to the type of side chains used with ionic and nonionic contrast agents. As a result, these compounds differ in their viscosities and other properties. The interaction with other molecules also differs between ionic and nonionic agents and is affected by the type of side branches present. Within limits, however, for each group of contrast agents, viscosity varies directly with iodine concentration.

Commercial contrast agents also contain chelating agents, usually calcium edetate disodium, to chelate impurities and buffering agents to achieve an acceptable pH. Their action is more important during contrast agent manufacture than during clinical use.

The American College of Radiology (ACR) has published criteria for situations in which nonionic agents are preferred,² although in many practices this is a nonissue because nonionic agents are used almost exclusively. The nonionic agents are associated with less patient discomfort and thus result in less motion artifacts; this is an evident advantage, especially with complex examinations such as three-dimensional (3D) reconstruction.

Pharmacokinetics

After a bolus intravascular injection, the initial plasma iodine concentration is determined by contrast agent iodine concentration and injected volume. Ionic and nonionic contrast agents are eventually distributed throughout the extravascular, extracellular space, with intravascular and extravascular equilibrium achieved within 10 minutes after intravascular injection. They are excreted mostly by renal glomerular filtration.

After injection, the relative plasma iodine concentration in a particular vessel depends on dilution by blood, extravascular diffusion, and renal excretion; the first factor is most important during arterial and venous phase imaging, with extravascular diffusion playing a larger role during the parenchymal phase. In theory, a contrast agent can be designed to have fast or slow extravascular diffusion and rapid or slow renal clearance; an ideal blood pool agent should have slow extravascular diffusion. In practice, with an equivalent iodine dose, nonionic agents achieve greater initial peak vascular enhancement than ionic agents, but subsequent blood iodine concentrations and parenchymal opacification are similar for the two types of agents (except renal visualization). Ionic and

nonionic agents have similar extravascular diffusion rates. Extensive literature is available on relative time-dependent blood iodine concentrations and renal excretion of various contrast agents.

Dynamic CT scanning after a single bolus injection relies on the enhancement of vascular structures above baseline. Correct arterial phase timing is obtained by injecting an initial test dose or using automatic bolus tracking. One mg iodine per gram of tissue corresponds roughly to an increase of 30 Hounsfield units (HU), which is about the limit for detection. In general, it is desirable to have sufficient iodine concentration in the vascular structures of interest to elevate them above baseline by up to 100 HU. With this degree of enhancement, major vessel thrombi are detected and vascular fistulas and related conditions evaluated. Whether early dynamic scanning (arterial phase) is superior to portal venous phase or even delayed scanning after contrast equilibration depends on the organ in question and information sought. For the liver, these arterial and portal phase time window are roughly 20 to 30 seconds. These short time intervals are readily achieved with MDCT.

A typical CT examination consists of a precontrast scan, followed by scanning after the initial bolus reaches the structure of interest. A relatively large-caliber venous catheter and power injector provide reproducible injection rates, keeping in mind that prediction of bolus arrival is somewhat empiric because, among other factors, decreased cardiac output can prolong vascular flow times.

Intravascular contrast agents cross the placenta, are excreted in breast milk, and affect fetal and infant thyroid function. If feasible, alternate studies should be considered during pregnancy. Breast-feeding should be stopped for 1 to 2 days after contrast injection.

Acute Adverse Reactions

Only a brief summary of contrast reactions and their therapy are provided here. More detailed information is available from ACR² and European Society of Urogenital Radiology (ESUR)³ publications.

The nonionic contrast agents have a considerably lower osmolality than the ionic agents; adverse reactions caused by hyperosmolality are therefore reduced with the nonionic agents. Hyperosmolality is also related to vasodilation of the involved capillaries. Nonionic contrast agents induce less hypotension than ionic agents.

Risk factors for acute renal failure include diabetes mellitus with decreased renal function, renal insufficiency, dehydration, and use of a high dose. Atopy confers an increased risk to contrast reactions, but allergies to shellfish appear not to increase the risk of reaction.⁴ Iodinated contrast agents are contraindicated in patients with obvious hyperthyroidism. Also, these agents should be avoided for 2 months prior to thyroid isotope imaging or radioactive thyroid therapy.⁴

Types of Reactions. Acute reactions vary from minor effects to severe and life-threatening. Sensations of warmth, nausea, and vomiting appear to be a direct side effect to contrast. Reactions such as mild changes in blood pressure or mild wheezing are often self-limiting or may progress to more severe reactions. An arbitrary but useful grading of contrast reactions is mild, moderate, severe, and fatal. Compilations of reactions to ionic contrast agents in the 1970s and 1980s revealed a risk of severe

reaction to be 1 in 1000 to 4000 studies. Types of reactions are similar with ionic and nonionic agents. In general, the risk of adverse reactions varies with contrast osmolality, so fewer reactions occur with nonionic agents than with ionic agents. In particular, the risk of severe adverse reactions is lower with nonionic contrast agents.⁵ Deaths have occurred with both ionic and nonionic agents.

At times, urticaria and even more severe reactions do not represent a classic antigen-antibody reaction but are secondary to histamine or serotonin release induced directly by the contrast agent. However, histamine release is probably not the only factor involved in serious contrast reactions. Among other effects, contrast agents activate the complement system, which acts as a host defense, and is related to coagulation abnormalities and bradykinin release. Overall, only a minority of unpredictable reactions mimics immunoglobulin E (IgE) hypersensitivity, probably secondary to an antigen-antibody reaction. How to classify the rare bowel wall edema is not clear.⁶ Iodide mumps is a rare delayed reaction to iodine-containing contrast media.

Some reactions are disease specific. IV contrast agents in the presence of a pheochromocytoma can lead to catecholamine release and acute hypertension. In this setting, the onset of such hypertension should suggest a pheochromocytoma.

Over the years, many radiologists have avoided the use of intravascular contrast agents in patients with sickle cell disease, although the prevalence of adverse reactions has not been established. Over an extended period, bottled hyperosmolar contrast agents can leach allergens from rubber stoppers. As a rule, contrast-containing vials and bottles should be stored in an upright position.

Premedication. The specific allergen responsible for iodinated contrast sensitization is unknown. It is difficult to prove that iodine is responsible for hypersensitive contrast reactions, a common assumption. A myosin protein rather than iodine is believed to be the allergen responsible in shellfish. Rather than ask a patient about iodine allergies, a more appropriate question appears to be whether drug allergies are present. On a practical level, the cause of an adverse reaction is often not sought, and the reaction is simply labeled as allergic, hypersensitive, or anaphylactic.

No reliable blood test detects patients who are allergic to contrast media. Risk factors associated with a contrast reaction include asthma and a history of prior reaction to contrast. However, even these are unpredictable, and a patient manifesting a severe reaction may have had prior intravascular contrast with no adverse reaction. Although patients with urticaria-like reactions have increased plasma levels of prekalikrein and α_2 -macroglobulin and lower levels of C1-esterase inhibitor, their predictive value is limited because of normal variation.⁷ Pretesting with a small dose of contrast was once popular but has been abandoned as having little or no value. Acute reactions have developed after less than 1 mL of administered contrast.

In a multi-institutional study involving ionic contrast agents, pretreatment with methylprednisolone, 32 mg, 12 hours and 2 hours before contrast injection, significantly reduced the risk of reactions.⁸ With this two-dose regimen, the number of reactions in patients receiving ionic contrast agents approximated those seen with nonionic agents and no pretreatment. Premedication is often considered for patients who have had

a previous reaction to a contrast agent. Regimens that have been proposed range from 3 days to immediately before a scan. At the University of Rochester, we recommend that patients who have had a significant prior reaction to IV contrast agents be pretreated with 50 mg of prednisone orally every 12 hours, for a total of three doses, with the last dose given approximately 1 hour before the examination, and 25 to 50 mg of diphenhydramine hydrochloride (Benadryl) orally, 2 hours before the examination.

The prevalence of seizures after IV contrast injection is increased in patients with brain metastases. Capillaries in brain metastases do not exhibit normal blood-brain barrier integrity and are permeable to a contrast agent. To decrease the risk of seizures, it has been suggested that these patients be premedicated with diazepam, 5 mg IV, before contrast administration.⁹

Treatment of Reactions. Any physician injecting a contrast agent intravascularly can expect to encounter a broad spectrum of reactions, from mild to severe, and must be prepared to deal with them. In general, mild reactions such as flushing or mild urticaria require no treatment, and most reactions resolve spontaneously. Similarly, nausea and vomiting require general support and observation only. If symptoms occur before all the contrast agent has been administered, the rate of injection should be slowed or the injection postponed until symptoms clear.

Early IV access should be established. The catheter used for contrast injection should be kept in place, ensuring intravascular access until the possibility of a reaction has passed. With progressive hypotension, it becomes increasingly difficult to cannulate a peripheral vein.

Moderate urticaria developing in the absence of other significant symptoms can be treated with diphenhydramine, 25 to 50 mg, orally or injected. With more severe urticaria, one should also consider an H₂ blocking agent such as cimetidine (Tagamet), 300 mg injected slowly (diluted) IV. For severe urticaria, epinephrine, 0.1 to 0.3 mL (1:1000) should be given subcutaneously unless contraindicated. If needed, the dose can be repeated in 15 minutes. Epinephrine should be used with caution in older patients who have underlying cardiovascular disease; electrocardiographic monitoring should be considered for these patients.

Severe reactions, such as severe bronchospasm, convulsions, or significant cardiopulmonary reactions, require prompt and vigorous therapy. Bronchospasm and laryngeal edema generally respond to subcutaneous epinephrine. If needed, the epinephrine dose can be repeated. Diphenhydramine and corticosteroids, such as hydrocortisone, 100 to 300 mg IV, are also often used. Oxygen should be administered by mask or nasal cannula. Beta agonist inhalers alone may be beneficial for mild bronchospasm or can be used in conjunction with aminophylline therapy. With refractory bronchospasm, aminophylline, 250 to 400 mg diluted in dextrose and water, can be administered IV over a 10- to 20-minute period. Aminophylline should be used with caution because it could exacerbate coexisting hypotension. Tracheal intubation should be considered early in the course of these symptoms; later, severe laryngeal edema may make intubation difficult if not impossible.

Because the treatment of hypotension in the settings of tachycardia and bradycardia is different, the pulse rate should

be monitored. A pulse may not be palpable in a hypotensive patient; cardiac auscultation or electrocardiographic monitoring may be necessary.

Hypotension in the absence of other major signs of an anaphylactic reaction should initially be treated with oxygen, leg elevation, and rapid administration of IV fluids. Epinephrine should be considered, keeping in mind that fluid therapy alone may be sufficient therapy. Although subcutaneous epinephrine injections are adequate for a mild to moderate reaction, IV administration is needed for moderate to severe hypotension. For IV administration, epinephrine should be diluted to 1:10,000 and 1.0 to 3.0 mL administered slowly. The dose can be repeated in 15 minutes, and the rate of injection can be titrated to achieve the desired result. A vasopressor agent such as dopamine, 2 to 5 $\mu\text{g/kg/min}$, can be added to sustain blood pressure. For unresponsive hypotension, other agents are available for treatment of underlying shock. An H₂ blocker such as cimetidine can be added, 300 mg in dextrose and water, infused slowly. Similarly, diphenhydramine, 25 to 50 mg, can be injected IV. Corticosteroids are also often used, with a typical dose of hydrocortisone being 500 mg IV. Steroids probably have no immediate effect on a reaction; their main use is to decrease delayed reactions.

At times, hypotension can be corrected with vigorous hydration alone, keeping in mind that overhydration of patients with possible underlying cardiovascular and/or renal disease also carries a risk. Thus, the initiation of therapy by adequate hydration is reasonable, but appropriate pharmacologic therapy should be instituted without undue delay.

Hypotension in the presence of bradycardia suggests a vagal reaction. Some patients respond to being placed in a Trendelenburg position. Hypotension in these patients should be treated with rapid IV infusion of isotonic saline. Oxygen should be administered. Bradycardia can be treated with atropine (0.5 to 1.0 mg IV), with the dose repeated every 5 minutes, to a maximal total dose of 3.0 mg.

Some patients receive long-term therapy with a beta blocker such as propranolol. A contrast reaction in these patients can be confusing because, even in the setting of anaphylactic shock, a beta blocker–induced bradycardia can persist. IV glucagon, 1.0 mg or more, may be useful for bradycardia. Dopamine is also effective. Doses of epinephrine that are usually administered may not be effective in reversing this hypotension.

Emergency cardiopulmonary resuscitation is necessary for cardiovascular collapse. Refractory seizures are treated with IV diazepam (Valium) and/or phenobarbital.

Contrast extravasation is treated by extremity elevation, warm or cold compresses and, if extensive, a plastic surgery consultation. Hyaluronidase, an enzyme that breaks down interstitial barriers, has been injected into the extravasation site by some investigators, but its impact on tissue healing is still not clear.

This discussion is only meant to be a guide. The treatment of all reactions should be individualized.

Contrast-Induced Nephropathy. The pathogenesis of contrast-induced nephrotoxicity is incompletely understood, but it is believed that a number of intrinsic renal events lead to renal medullary ischemia, usually augmented by a reduced intravascular volume.¹⁰ Direct cytotoxicity, oxidative tissue damage, and apoptosis are contributing factors. This nephrotoxicity is manifested by a significant rise in the serum creatinine level.

Various authors use different definitions of significant, with the ESUR guidelines using a creatinine level increase of more than 25%, or 44 $\mu\text{mol/L}$ (0.5 mg/dL), within 3 days.³ A transient nonoliguric decrease in renal function lasting up to 3 weeks is more common than the more ominous oliguric manifestation, which may require hemodialysis.

Risk factors for nephrotoxicity appear to be multifactorial and include preexisting renal insufficiency, diabetes, dehydration, cardiovascular disease, advanced age, myeloma, hypertension, hyperuricemia, and possibly contrast osmolality and dose. Patients at the greatest risk for acute renal failure are diabetics with preexisting renal insufficiency. Precaution is also necessary with treatment by agents such as nonsteroidal anti-inflammatory drugs (NSAIDs), aminoglycosides, cyclosporin, or even sulfonamides; underlying nephrotoxicity is a common pathway.

In diabetics with underlying cardiovascular or renal insufficiency, metformin, a biguanide antihyperglycemic agent, is associated with lactic acidosis and resultant increased mortality. This association appears to be indirect and probably involves underlying renal insufficiency. However, enough patients taking metformin and receiving IV contrast have developed lactic acidosis to prompt the U. S. Food and Drug Administration (FDA) to issue a warning—metformin should be discontinued before or at the time of contrast use for 48 hours after the procedure and reinstated only if renal function remains normal. However, substantial inconsistencies exist in the guidelines.¹¹ Adequate hydration should be maintained.

Because iodinated contrast agents are not protein-bound (except for cholangiographic agents), they can be dialyzed. In patients on hemodialysis, additional hemodialysis sessions are generally not necessary.

The most important preventive measure is to ensure that the patient is well hydrated. If IV hydration is necessary, some evidence suggests that the IV use of sodium bicarbonate hydration is superior to sodium chloride.^{12,13} Other guidelines include the use of low-osmolar contrast, discontinuing nephrotoxic drugs for at least 24 hours, and consideration of alternate imaging in high-risk patients. The osmotic diuretic mannitol does not provide any benefit; this loop diuretic furosemide exacerbates renal dysfunction.² Currently, it is probably safe to assume that diuretics do not offer any protective effect, and anecdotal evidence even suggests that diuretics should be stopped prior to a contrast study.¹⁴

N-acetylcysteine, an antioxidant, appears to diminish contrast-induced renal toxicity,^{15,16} although some have questioned its renal benefit.¹⁷ Many of these studies have involved coronary angiography and differ in methodology from contrast CT. The role for theophylline is less well established.

Hemodialysis after contrast use in preexisting renal failure patients is not thought to be warranted. Hemofiltration in chronic renal failure patients, on the other hand, has caused less creatinine level increase than in controls.¹⁸ The complexity of this procedure and the cost of hemofiltration limit its use to select patients.

IODINATED OIL

Intra-arterial iodized poppy seed oil (Ethiodol or Lipiodol) is used for several indications:

1. As a CT diagnostic agent for liver tumor detection, especially hepatocellular carcinoma.

Often used as a gold standard, it detects more tumors than other imaging modalities. Nevertheless, a study of explanted livers revealed that pretransplantation iodized oil CT tumor sensitivity is still rather low. Also, one should keep in mind that iodized oil is retained by some benign tumors, even hemangiomas.

2. Ethiodol is often included as a chemoembolization ingredient when injecting into a tumor feeding artery.

This acts as a chemotherapeutic agent carrier and, because of its high viscosity, is a temporary embolizing material that prolongs chemotherapeutic agent contact with a tumor. Ethiodol remains within tumor neovascularity much longer than in normal liver parenchyma and thus acts as a marker.

3. Occasionally, ethiodol is injected during percutaneous radiofrequency ablation of hepatocellular carcinomas.¹⁹

This aids in the CT delineation of extent of coagulation necrosis.

For a number of reasons, intra-arterial iodized oil is considerably more popular in the Far East than in the West.

OTHER AGENTS

Several reports have described the use of gadolinium (Gd)-based contrast agents for CT imaging in patients with renal insufficiency or prior severe reaction to an iodinated agent. One should keep in mind, however, that the pharmacokinetic properties of gadopentetate dimeglumine (Gd-DTPA), with only one gadolinium ion, are similar to iodinated agents containing three to six iodine atoms. Also, the toxicity of gadolinium agents, at doses achieving equivalent x-ray stopping power, is greater than that of nonionic iodinated agents. This is in distinction to the use of approved lower gadolinium MRI doses, which are insufficient for useful x-ray contrast, but have negligible nephrotoxicity.³ The ESUR position is that gadolinium-based contrast agents are more nephrotoxic than iodinated contrast agents in equivalent x-ray attenuation doses.³

Carbon dioxide is a viable angiographic contrast agent for certain digital vascular indications in the abdomen. It has been used as a guide for vascular interventional procedures. It displaces blood, forms a gaseous column, and is cleared by the lungs.

Apart from MR, viable abdominal reticuloendothelial contrast agents have eluded clinical development. The first such agent, thorium dioxide (Thorotrast), used until the 1950s, has left a painful and sorry legacy. Iodinated oily emulsions accumulate in the liver, spleen, bone marrow and, to a lesser extent, in other organs, long enough to permit CT imaging, but high toxicity and low specificity led to their abandonment. Colloidal iodine or emulsified perfluorooctyl bromide particles are also incorporated in reticuloendothelial cells. Most studies of emulsified perfluorooctyl bromide took place in the 1980s, and its use has lost favor since then.

Liposomes are taken up by the reticuloendothelial system, and considerable effort has been expended to encapsulate water-soluble iodinated contrast agents inside liposomes. Research activity peaked during the 1990s but, in spite of occasional more recent papers, pronounced adverse reactions limit the use of liposomal CT contrast agents in humans. Most current reticuloendothelial contrast research revolves around MRI agents.

Gastrointestinal Contrast Agents

BARIUM SULFATE

Barium sulfate is a white crystalline powder having a molecular weight of 233. Because of its specific gravity of 4.5, patients tend to comment that a cup of barium suspension is "heavy." The terms *thick* and *thin* should only be used when referring to viscosity. They should not be used to signify radiodensity, which has many other causative factors.

Although barium sulfate itself is inert and does not support bacterial growth, some additives in commercial preparations are organic. When a container is opened or reconstituted with tap water, the suspension should be refrigerated if it is to be kept overnight. Although many commercial formulations contain preservatives, bacterial contamination can and does occur.

Certain commercial formulations are advertised as being applicable throughout the GI tract. Invariably, these represent a compromise. The GI tract varies in pH, in composition of mucus, and in type of mucosa, and optimal coating in one part does not mean that a similar coating can be expected in another. Coating the mucosa with barium or simply opacifying the lumen requires different barium formulations.²⁰ The large-particle, high-density barium suspensions designed for double-contrast use should not be simply diluted and used for single-contrast studies. Ingesting such a diluted suspension causes rapid barium particle sedimentation, with the nondependent lumen containing little barium; lesions on the nondependent wall can therefore be missed. Products designed primarily for single-contrast examinations, on the other hand, can be diluted considerably before any settling occurs, mainly because they contain relatively small barium particles.

Ingestion of a barium sulfate suspension tends to be constipating. Currently, commercial barium products have additives that minimize this effect, and the formation of a bariolith is rare.

PHARYNGOGRAPHIC AGENTS

Pharyngeal radiography was already established in the 1960s, when cineradiography became popular to evaluate dysphagia. Although conventional or digital radiography produces high anatomic resolution, dynamic swallowing is best evaluated with video fluoroscopy or cineradiography. This pharyngogram, commonly called a modified barium swallow, evaluates oropharynx anatomy and function using contrast agents of varying consistencies.

After a stroke, appropriate patient feeding without inducing aspiration can be determined by using barium suspensions of different viscosities and barium-coated food. Contrast consistencies used range from barium-coated crackers to a viscosity approaching that of water. To improve patient acceptance, some investigators have developed their own contrast agents such as barium pudding or barium honey. Anatomic detail is best studied with high-density barium products such as the 250% w/v suspensions designed for gastric double-contrast examinations. Fistulas are also best studied with this type of contrast agent. A barium paste can also be used to study anatomy, but the high paste viscosity limits its application in fistula detection. The volume of barium used should be individualized. Thus, with suspected aspiration, a several-milliliter bolus is swallowed

initially; if no aspiration is detected, the bolus is gradually increased in volume.

The oropharynx handles high- and low-viscosity liquids differently, so pharyngeal function should be studied with high- and low-viscosity barium suspensions. The low-viscosity suspension should have a viscosity approaching that of water, whereas the high-viscosity suspension should be similar to a thick milkshake. It should be emphasized that some high-density double-contrast barium products are relatively fluid and are not applicable as high-viscosity preparations.

A tracheoesophageal fistula is easier to detect fluoroscopically with the patient in the lateral position. With the patient in a frontal position, it may not be possible to determine whether barium in the trachea was aspirated or flowed through a fistula.

UPPER GASTROINTESTINAL TRACT STUDIES

Studies of the esophagus consist of single-contrast, double-contrast, and mucosal relief views, together with fluoroscopic evaluation of motility. Normal esophageal tonicity leads to lumen collapse when a primary peristaltic wave has passed. Therefore, regardless of which method is used, the study must be performed reasonably quickly.

Some patient symptoms are reproduced by using a cold contrast suspension or acidic contrast. Although some have found acidified contrast useful, it is not commonly used.

Sufficient air is introduced into the esophagus for a double-contrast study in some patients with poor esophageal motility or those with gastroesophageal reflux. In most patients, however, an additional negative contrast agent is necessary to obtain double-contrast views. Solid gas-producing tablets, powder, or liquid effervescent agents are used. These contain sodium bicarbonate and an acid, such as tartaric acid or citric acid, which, in the presence of a liquid, produce carbon dioxide. About 400 to 500 mL of gas is necessary for adequate esophageal and gastric distention. One technique is to have the patient drink, in quick succession, first one and then another liquid effervescent solution, followed immediately by 60 to 120 mL of a barium suspension. The two effervescent agents distend the esophagus by releasing carbon dioxide, and barium then coats the esophageal mucosa.

The high-density, low-viscosity barium products designed for the stomach and duodenum also coat the esophagus wall. Visualization of the esophagus is impaired if barium is ingested before effervescent agents. On the other hand, the quality of the gastric mucosal coating is improved if the barium suspension is given first. The sequence of ingestion can be tailored to the patient's symptoms—if esophageal disease is suspected, the effervescent agents are given first; if gastroduodenal disease is suggested, the barium suspension is given first.

Esophageal varices tend to be more prominent and their detection easier if the esophageal lumen is collapsed. Although high-density, low-viscosity barium products detect larger esophageal varices, commercially available barium pastes are recommended. Some of these pastes are too viscous and tend to flow in a bolus; these should be diluted with water so the paste viscosity is similar to that of honey.

In a patient with acute dysphagia, an esophagram can be therapeutic. With the patient upright, the weight of a barium column can dislodge a foreign body into the stomach. Liquid effervescent agents increase the intraluminal esophageal

pressure and may also push a foreign body into the stomach. This technique should be performed with care to avoid perforation. Glucagon has also been proposed to help relieve spasm, although it is not clear whether pharmacoradiology has a significant role in acute dysphagia.

Commercial barium sulfate tablets with a diameter of 12 mm are available and are useful to evaluate subtle esophageal strictures. For results to be meaningful, the patient should be at least in a 45-degree upright position and at least 60 mL of water should be ingested with the tablet. Tablet transit time through the esophagus normally is less than 20 seconds. These tablets contain 650 mg of barium sulfate plus additives. The tablets dissolve in the esophagus or stomach (Fig. 1-1). Relatively fresh tablets should be used because older tablets take longer to dissolve.

It has been proposed that barium tablets be administered routinely during chest radiography because tablet retention in the esophagus is associated with the presence of structural or functional esophageal abnormalities, but this technique is not widely used.

In patients with suspected esophageal perforation, study of the esophagus with a water-soluble agent may not detect a subtle leak. Thus, administration of higher density barium sulfate enables detection of leaks that might otherwise be missed.²¹ For this part of the examination, barium suspensions varying from 35% to 80% w/v are used. Residual barium in the mediastinum does not result in clinically detectable

Figure 1-1 Barium sulfate tablet proximal to a stricture. A previous esophagram suggested narrowing at this site, and the tablet confirms this finding. (From Schabel SI, Skucas J: Esophageal obstruction following administration of "aged" barium sulfate tablets—a warning. *Radiology* 122:835–836, 1977.)

mediastinitis and does not interfere with subsequent radiographic evaluation.

High-density, low-viscosity barium preparations specifically designed for the upper GI tract produce best double-contrast results. A volume of 60 to 120 mL of a 250% w/v suspension is generally sufficient. A good barium formulation should result in routine identification of the *areae gastricae*. Small cancers, ulcers, gastritis, and duodenitis are readily detected during a high-quality examination.

When appropriate double-contrast gastric views have been obtained, a lower density barium suspension is ingested for subsequent single-contrast evaluation. For this part of the examination, barium suspensions varying from 35% to 80% w/v are used. Various external compression paddles are available and are helpful in obtaining mucosal relief views.

SMALL BOWEL STUDIES

A number of techniques have been developed to study the small bowel, such as conventional antegrade study, enteroclysis, retrograde ileography, peroral pneumocolon, and CT and MR enterography. The type of examination performed varies with clinical indication. Specific contrast agents have been developed for each type of study.

An antegrade examination is the simplest and most traditional way of studying the small bowel. Serial small bowel radiographs are obtained after the patient ingests a barium suspension. The primary contrast agent requirement is that it does not flocculate or precipitate during transit. The barium does not coat the mucosa; visualization is obtained primarily by filling the bowel lumen with the barium suspension. A 40% to 60% w/v suspension is typical. Many radiologists prefer a volume of 500 to 800 mL.

Contraindications to an antegrade barium study are suspected colonic obstruction or bowel perforation. A number of clinicians hesitate to request a barium study in the setting of small bowel obstruction and prefer to wait until the obstruction clears. Such an approach is analogous to obtaining a chest radiograph only after a pneumonia clears. Small bowel obstruction is not a contraindication. Barium proximal to a small bowel obstruction continues to stay in suspension, and barium inspissation does not occur. With a small bowel obstruction, an antegrade study with barium is safe and not only can detect the site of obstruction but also suggest a cause.

In enteroclysis (small bowel enema), contrast is injected through a steerable catheter directly into the small bowel, so the flow-limiting function of the pylorus is bypassed. The barium suspension can be infused by gravity, hand-held syringes, or an infusion pump. Typical infusion rates are 75 to 100 mL/min, although the flow rate should be individualized. If the rate is too slow, excessive peristalsis results in a study similar to a conventional antegrade small bowel examination. With a flow rate that is too high, overdistention leads to bowel atonia and lack of progression.

It is debatable whether single-contrast or double-contrast enteroclysis yields better results. For the double-contrast portion, many U.S. investigators use a solution of methylcellulose in water ($\geq 0.5\%$). Methylcellulose helps propel a barium suspension ahead of it. Water can be used as the second contrast agent, although water tends to wash off barium adhering to the mucosa. The total volume of the two contrast agents is tailored for each examination; in some patients, up to 2 L are required.

The contrast agents are instilled until a lesion is detected or contrast reaches the right colon. If needed, glucagon is administered to induce hypotonia.

Air as a second enteroclysis contrast agent, used more commonly in Japan and Europe, results in considerably more radiographic contrast than obtained with methylcellulose. Air does not propel the barium ahead of it as quickly as methylcellulose; it tends to percolate through barium-filled loops of bowel. Nevertheless, with overlapping bowel loops, as is common in the pelvis, infusion of air is often helpful. Air bubbles can be confusing, although some think that better diagnostic results can be achieved with air, even in patients with inflammatory bowel disease.

Several tubeless enteroclysis techniques have been described. One simple method is to initially perform a conventional small bowel study, but when barium approaches the cecum, the patient swallows additional effervescent agents, turns prone, and the table is turned into a 20- to 40-degree Trendelenburg position. Efflux of gas results in a double-contrast small bowel study. A tubeless double-contrast small bowel technique consists of effervescent granules coated with an acid-resistant lacquer. Gas is released directly into the small bowel lumen.

Barium formulations specifically designed for enteroclysis provide the best results and are commercially available. For a single-contrast study, a barium suspension having a specific gravity of about 1.25 (equivalent to $\approx 35\%$ w/v) is typical. For a double-contrast study, the barium suspension should be in the range of 50% to 95% w/v.

Retrograde ileography consists initially of a single-contrast barium enema, but infusion of barium is then continued retrograde into the ileum. Because flow is controlled by the examiner, the ileum can be readily studied without overlapping loops from the more proximal small bowel. Barium is instilled until the region in question is reached. Premedication with glucagon increases patient comfort and also relaxes the ileocecal valve. If a redundant sigmoid colon obscures part of the small bowel, the barium enema can be followed by a saline enema; such a solution pushes barium ahead of it and results in a see-through effect. A 20% to 25% w/v barium suspension is typical for such a study.

It is not unusual to achieve a double-contrast study of the terminal ileum during a double-contrast barium enema, especially if glucagon is used. This type of study is useful in suspected ileal Crohn's disease or gynecologic malignancies involving the ileum.

A peroral pneumocolon, consisting of antegrade and retrograde components, is designed to evaluate the distal ileum or right colon. Initially, a conventional antegrade small bowel examination is performed. When barium outlines the terminal ileum, air is instilled through the rectum to obtain double-contrast views of the distal small bowel or proximal colon. This study can also be combined with enteroclysis. Routine use of a hypotonic agent is helpful.

BARIUM ENEMA

Single-contrast and double-contrast techniques are well established methods of evaluating the colon. Numerous studies have compared the relative accuracy of a single-contrast versus double-contrast barium enema. Some radiologists prefer a single-contrast study in older or debilitated patients.

Dry and liquid barium formulations are commercially available. If dry barium-prefilled enema bags are used, the amount of water added and degree of subsequent shaking to achieve wettability should be standardized. The level marking on the enema bag should not be used to gauge the amount of water needed; resultant dilutions tend to be erratic. Liquid barium-filled enema bags should be kept on their sides because considerable settling can occur if bags are stored before use.

A 12% to 25% w/v barium suspension is commonly used for single-contrast barium enemas. The main requirement of the barium suspension is that it neither flocculates nor settles during the examination. Because the sedimentation rate depends, in part, on the amount and type of additives present, some products that are well suspended at higher concentrations settle readily when diluted. If there is doubt about a commercial product's sedimentation rate, a radiograph obtained with a horizontal x-ray beam should reveal any settling tendencies.

Double-contrast barium enema suspensions should consist of relatively high barium concentrations but should still be sufficiently fluid to flow readily through enema tubing. Their viscosity is greater than that of the lower concentration barium formulations designed for single-contrast studies. The resultant mucosal coating should be uniform, without undue artifacts. The suspension should not dry out while an examination is in progress. These barium formulations are generally in the range of 60% to 120% w/v, with 85% being typical.

Even when all conditions are standardized, the subsequent mucosal coating can vary among practices because of variations in local water hardness and type of water used (distilled water or cold or hot tap water). Premixed liquid formulations are available to avoid these variations. The barium suspension is simply poured into an enema bag without further dilution.

Some radiologists perform colonic lavage before a barium enema. This lavage invariably results in water retention and subsequent dilution of the barium suspension. Barium manufacturers recognize this difference and market two different preparations; the one designed to be used after colonic lavage has a barium suspension with a slightly greater specific gravity.

Tumors can be difficult to detect in a segment involved by severe diverticulosis. This segment can be further studied if the double-contrast barium enema is followed by a methylcellulose enema.

WATER-SOLUBLE CONTRAST AGENTS

Indications

Water-soluble organic iodine compounds designed for the GI tract were introduced in the 1950s. Ever since, controversy has surrounded the relative merit and role of these agents. These compounds do not coat the GI mucosa; rather, they provide bowel visualization simply by passive filling of the intestinal lumen.

For most bowel examinations, experienced radiologists prefer barium suspensions. Some surgeons, however, are still being taught about the purported dangers of barium and insist on the use of water-soluble agents. Stimulation of peristalsis in postoperative patients and lack of radiographically visible sequelae of spill from the GI tract are reasons cited by some surgeons for their preference for water-soluble agents.

Water-soluble agents are indicated if an acute perforation is suspected. The examination generally confirms or excludes a

perforation, with the realization that small perforations can be missed. Similarly, walled-off perforations or a perforation in an area of spasm can be difficult to detect, and it may be necessary to complete the examination with barium.

With a chronic or loculated perforation, the higher radiographic visibility of barium often yields more information than that obtained with water-soluble contrast agents. Thus, a chronic abscess or other cavity in continuity with the bowel lumen can be safely studied with barium. If there is a possible communication with the peritoneal cavity, however, water-soluble agents are preferred.

Meconium ileus and meconium plug syndrome can be treated with an iodinated contrast enema. The patient should be well-hydrated.

Some surgeons treat postoperative adynamic ileus with oral, full-strength, ionic contrast agents, but studies on these types of agents have been limited. Also, a hypertonic fluid proximal to a mechanical obstruction results in further distention.

Contrast Agents

In general, to achieve adequate radiographic opacification of most GI structures, at least a 60% solution of an ionic contrast agent is needed. The resultant iodine concentration is 282 to 292 mg/mL for the more commonly used commercial products, with a resultant osmolality of about 1500 mOsm/kg, or approximately five times that of serum. Because of this hyperosmolality, fluid is drawn into the bowel lumen, and diarrhea is common after their use. These agents stimulate intestinal peristalsis, so faster visualization of the distal small bowel can be achieved than with barium sulfate. The need for a faster examination should be balanced against decreased radiographic contrast obtained with these agents. In general, intraluminal dilution leads to poor visualization of the small bowel.

Some commercial ionic contrast agents designed for oral use, such as the diatrizoate meglumine preparations Gastrografin and oral Hypaque, contain flavoring agents. These are preferred to the nonflavored products, which are designed primarily for IV use.

Nonionic contrast agents with an iodine concentration of approximately 300 mg/mL have an osmolality of 600 to 710 mOsm/kg, which is less than 50% of that of ionic agents. At this concentration, however, they are still hyperosmolar compared with serum.

Ideally, one of the nonionic agents should be used whenever a water-soluble agent is indicated for evaluation of the GI tract; for certain examinations, some radiologists use nonionic agents. If a perforation into the pleural or peritoneal cavity is suspected in an adult and aspiration is not a consideration, nonionic agents probably do not offer any major advantage over their ionic counterparts. Nevertheless, some leaks are better defined with barium than water-soluble agents. In studies of the GI tract in infants and children, in whom perforation is not an issue, barium rather than a water-soluble is the preferred contrast agent.

NEGATIVE CONTRAST AGENTS

When performing double-contrast GI studies, the cheapest second contrast agent is air. Excellent double-contrast esophageal views can be obtained if the patient swallows air together with the barium preparation.

One commercial preparation incorporated carbon dioxide directly in the barium suspension; when the patient drank this “bubbly barium,” carbon dioxide was released into the esophagus and stomach. The effect was similar to that of drinking a bottle of club soda, and this product did not achieve ready acceptance.

Effervescent tablets, granules, and powders are commercially available. They produce carbon dioxide on contact with water and most are satisfactory in achieving adequate gastric and duodenal distention. There is, however, considerable variation in their dissolution time. Most commercial effervescent powders and granules come in single-dose packages. In clinical use, the patient places the effervescent agent in the mouth and uses small amounts of water to wash it down. This is immediately followed by a barium suspension. The swallowed gas is used for double-contrast views of the stomach and duodenum.

Liquid effervescent agents, consisting of separate acid and base solutions, can be prepared locally by a hospital pharmacy. The acid portion consists of citric and tartaric acids and the base portion is sodium bicarbonate. A dose of 12 to 15 mL is satisfactory for most patients.

Carbon dioxide is used by some in place of air for double-contrast barium enemas and CT colonography. Carbon dioxide is absorbed faster than air. Whether a gas or air is used probably does not influence examination quality although, with all other factors remaining constant, colonic distention is less with carbon dioxide compared with air.

Some double-contrast preparations result in excessive gas bubbles. An antifoam agent should be added empirically if these occur on a regular basis. Although many commercial barium preparations already include such an agent, in some areas the amount is not sufficient. A commonly used antifoam agent is dimethyl polysiloxane (simethicone); the addition of 1.5 mL of simethicone (equivalent to 100 mg) is often sufficient to eliminate bubbles.

GASTROINTESTINAL COMPUTED TOMOGRAPHY AGENTS

The term *double-contrast abdominal CT* is used by some to signify the use of IV and oral contrast. However, this is a misuse of the traditional connotation of double contrast and is best avoided to prevent confusion.

Full-strength barium preparations should not be diluted to the low concentrations needed for CT. The barium particles settle out after ingestion of such a dilute solution, leading to inhomogeneous bowel lumen opacification. The uppermost part of a loop of bowel may not contain enough barium for visualization, and excess barium in the dependent portion results in streak artifacts.

Stable but low-concentration barium formulations specifically designed for CT are commercially available, with most of these brand names ending in *-cat*. Most CT barium products contain small particles that resist settling. Additives selected also prevent barium sedimentation. At the low barium concentrations used, barium particles do not coat the mucosa but simply provide lumen opacification.

An esophagus marked with a contrast agent aids in evaluating the mediastinum during chest CT. The low-concentration CT agents used in the rest of the GI tract do not opacify the esophagus long enough, although one option is to have the patient drink small sips of a conventional CT contrast agent

before each scan. More convenient is a high-viscosity, low-concentration barium paste, which provides prolonged esophageal coating.²² Mucosal adherence by such a paste is long enough to allow a typical CT examination to be completed. Ingested water is often a useful and satisfactory contrast agent for evaluation of the GI tract during helical CT.

The traditional method of opacifying the stomach and small bowel is to have the patient drink approximately 500 mL of a dilute CT contrast agent several hours before the examination, with a similar amount ingested immediately before scanning. Ideally, such an agent should differentiate bowel from surrounding structures without introducing artifacts. Use of a dilute iodine solution or a barium suspension is generally a personal preference. A 1% to 3% w/v barium sulfate suspension or a 2% to 5% solution of Gastrografin or similar iodinated agent is typical. One refinement (granted, little practiced) is to use a 2.0% barium concentration for jejunal opacification and a slightly lower concentration for pelvic structures. With slower CT units, an iodine solution produces fewer streak artifacts than barium, a problem of little consequence with multislice CT. Commercial barium suspensions tend to taste better than iodine solutions, a factor when examining children and nausea-prone cancer patients.

The iodine taste can be masked by adding sugar and various fruit extracts; although essentially sugar-free iodine contrast is available, barium products, in general, contain less sugar than corresponding iodine contrasts. At the dilutions used, the iodinated solutions are hypoosmolar, but some patients still develop diarrhea. The poor taste and hence poor acceptance of iodinated agents by patients can be partly overcome by the empiric addition of a flavored juice such as Kool-Aid.²³ At the dilutions used in CT, nonionic contrast agents do not have any real advantage over ionic agents.

With suspected pelvic disease, a contrast agent can be ingested the evening before the examination. Even if full-strength Gastrografin is ingested, overnight dilution in the bowel is sufficient to eliminate most streak artifacts. Better rectosigmoid opacification is obtained after ingestion of such a full-strength contrast agent than dilute barium, probably because hyperperistalsis is induced by the iodinated agent. Nevertheless, identifying the large bowel is less of a problem than identifying fluid-filled loops of small bowel on abdominal CT.

Both CT and MR enterography can detect Crohn's disease with somewhat similar accuracy.²⁴ Adequate CT bowel opacification can be achieved by using a 2% flavored barium suspension.

CT enteroclysis consists of bowel intubation and instillation of an iodinated contrast agent, dilute barium suspension, or methylcellulose suspension. Whether a positive or water-density agent is superior is not clear; an IV contrast agent to opacify bowel mucosa aids in lesion detection. Negative oral contrast agents designed specifically for CT enteroclysis have also become available. Also, with MDCT and coronal reconstruction now more readily available, retained bowel fluid often provides a sufficient marker, especially in dilated bowel loops.

If the imaging study is performed to evaluate a rectal lesion, a high-viscosity, low-volume barium paste may suffice; approximately 100 mL of a 3.6% w/v carboxymethylcellulose and 2% w/v barium sulfate paste mixture has been proposed in this clinical setting.²⁵

A basic question when protocoling an examination on multidetector CT is whether intraluminal water-density or

fat-density contrast, or even a gas, is superior to a positive contrast agent. Positive bowel contrast creates artifacts, especially with maximal intensity projection images of vascular structures. Also, bowel wall enhancement by IV contrast is useful for detecting bowel wall thickening, and a positive intraluminal contrast can obscure subtle lesions. As a result, MDCT studies can be performed with oral water-density or even negative contrast agents. Although adequate for gastric and duodenal distention because of its absorption from the bowel, ingested water does not readily distend the distal small bowel; use of a carboxymethylcellulose or polyethylene glycol solution inhibits absorption and improves distention (compared to water). A preliminary study of simethicone-coated cellulose (SonoRx, Bracco Diagnostics, Monroe Township, NJ), developed for oral use in upper abdominal ultrasonography, found no significant advantage over oral water in abdominal CT.²⁶

In the past, a number of fat density products, such as mineral oil, corn oil, and milk, and even a paraffin emulsion, were proposed for CT use, but these have had limited application. Residual bowel gas often serves as a marker, especially in the colon. If a nasogastric tube is in place, air can be injected into the stomach and small bowel. If excessive amounts of gas are present, imaging with window settings slightly wider than usual is helpful. 2D colonography and 3D virtual colonoscopy require colonic distention with a contrast agent; typically, air is used, and carbon dioxide is used less often.

ADVERSE REACTIONS

Barium Sulfate

Barium sulfate is poorly soluble in water. The constipating tendency of barium products is well known to most radiologists. Through the judicious use of additives, this side effect is minimized in most current formulations, although barium impaction in the colon is still occasionally encountered.

Aspiration of small amounts of commercial barium formulations is of little clinical significance. After barium aspiration, most is cleared from major bronchi and trachea within hours, although some is retained in the interstitium and in macrophages. This residue is generally not visualized on radiographs. Alveolarization of barium, however, can result in prolonged retention. If aspiration is suspected clinically, nonionic, sterile, iso-osmolar iodinated contrast can be used rather than barium.

Hypersensitivity reactions during GI examinations are rare, although they have been known to occur. Although barium sulfate is inert, commercial formulations contain numerous known proprietary additives.²⁷ These include stabilizing, flavoring, coating, and viscosity-varying agents and range from natural flavors and gums, such as lemon, pectin, and guar, to synthetic products, such as various methylcelluloses. Some radiologists may still be familiar with chocolate-flavored barium products, which are no longer used because of common allergies to chocolate. Anaphylaxis can be caused by carboxymethyl. Methylparaben and similar compounds, used as preservatives, can induce hypersensitivity reactions, but barium manufacturers have replaced them with more innocuous preservatives in most commercial barium products.

Reactions appear to be more common during double-contrast than single-contrast studies. Most reactions are mild and consist of urticaria or pruritus, although erythema

multiforme, respiratory complications, anaphylaxis, GI angioedema, and even death have occurred. Patients with asthma and severe food allergies appear to be at a slightly increased risk for these reactions, but the average radiologist will probably not encounter a hypersensitivity reaction to a barium product in a lifetime of practice.

The cause of hypersensitivity reactions during most barium studies is not known. In general, the incriminating agent is not sought and no testing performed in most patients who develop a reaction.

Esophageal perforation and spillage of barium into the mediastinum result in an inflammatory reaction, with barium persisting in the mediastinum for a prolonged period. Such prior extravasation can often be recognized radiographically as dense linear radiopacities, but no strong evidence exists that these sequelae have any clinical significance for the patient.

Most perforations associated with a barium enema occur in the rectum and are not immediately detected by fluoroscopy. Rectal perforations tend to result from injudicious insufflation of an enema balloon. A British survey over a 3-year period between 1992 and 1994 revealed a complication rate of 1 in 9000 and a death rate of 1 in 57,000.²⁸ Although 10% of patients with a bowel perforation died (3 of 30), the mortality was 56% (9 of 16) in patients developing a cardiac arrhythmia.

Spillage of barium into the peritoneal cavity can be secondary to a preprocedure perforation, such as in patients with ulcers. Some perforations, however, are associated with a barium study and can occur during an upper GI examination or barium enema, and even during enteroclysis. Initially, leukocytes are drawn into the peritoneal cavity, together with an inpouring of fluid. Profound hypovolemia develops if massive inpouring of fluid into the peritoneal cavity is untreated. Bacterial contamination during a perforation can result in overwhelming sepsis and shock within hours.

Immediate management of barium peritonitis includes infusion of large volumes of IV fluid. Antibiotics are administered because of associated bacterial contamination. Most patients undergo surgery, with an attempt made to evacuate barium from the peritoneal cavity. Invariably, barium crystals embedded on the peritoneal surface resist dislodgment. Attempts to remove barium particles with a wet sponge simply induces diffuse peritoneal bleeding.

Barium crystals incite an inflammatory reaction; eventually, these crystals become coated by a fibrin membrane, and extensive fibrosis and granulomatous tissue develop. Dense fibrosis can involve adjacent structures and, depending on location, subsequent ureteral obstruction or bowel deformity and stenosis develop. Perirectal fibrosis can narrow the rectosigmoid lumen and even mimic a carcinoma. Residual barium is identified with conventional radiography or CT. No evidence suggests that barium in soft tissues is a carcinogen (Fig. 1-2).

The barium intravasation can involve systemic veins and the portal venous system.^{29,30} Some patients have no predisposing factors to account for intravasation. Overall, barium intravasation is associated with a mortality rate of more than 50%.

Water-Soluble Agents

The risk of sensitivity reactions to oral iodinated contrast agents is considerably less than with intravascular injection. In young children and adults with hypovolemia, however, the introduction of large volumes of a hypertonic agent into the GI tract

Figure 1-2 Prior colonic perforation during a barium enema. Barium crystals are encased by dense adhesions that also involve bowel. (From Miller RE, Skucas J: *Radiographic Contrast Agents*. Baltimore, University Park Press, 1977, p 137.)

can result in hypovolemia, shock, and possibly death. In such a setting, adequate intravascular fluid replacement and the use of a nonionic contrast agent should be considered.

If aspiration or a tracheoesophageal fistula is suspected, hyperosmolar ionic contrast agents are contraindicated because they can induce pneumonia, pulmonary edema, or death. The nonionic agents are reasonable substitutes. In most adults, however, barium sulfate is the preferred contrast of choice.

Other Contrast Agents

Some reactions occur even before a contrast agent is instilled. Latex, used in some enema balloons, has been implicated in some reactions. The offending antigen in latex is believed to be a water-soluble, heat-stable protein. It is found on the surface of cured latex and probably is a contaminant of natural latex when it is obtained from the *Hevea brasiliensis* tree. In sensitive individuals, contact with skin leads to urticaria; contact with mucous membranes can result in more severe anaphylactic reactions. Currently, nonlatex and synthetic latex products are available.

Cholangiographic Contrast Agents

With normal renal function, only about 1% of an ionic or nonionic contrast agent dose undergoes hepatic excretion, which is insufficient for CT bile duct visualization. In the setting of renal failure, however, it is not unusual to detect gallbladder opacification, even with conventional radiography.

Cholecystography using oral cholecystographic agents has been supplanted by other imaging modalities and currently is rarely performed. Several commercial cholecystographic agents are available. To ensure oral absorption, they have hydrophilic and lipophilic properties; in blood, they are bound to albumin and, theoretically, should have high toxicity, but in

actual practice, adverse reactions are uncommon. They undergo enterohepatic circulation and occasionally delayed reactions are encountered.

IV cholangiographic agents undergo hepatocyte uptake and biliary excretion by active transport. They are excreted unchanged or after conjugation with glucuronic acid. These hepatocyte-specific liver contrast agents consist of triiodobenzene compounds which, by means of benzene ring substitutions, have had their hydrophilicity decreased to the point that they can now pass through membranes. Iodipamide meglumine (Cholografin) is the only agent available in the United States. Most of the injected contrast is bound to albumin; biliary visualization is generally evident about 15 minutes after the start of IV injection. One might assume that because cholangiographic agents undergo hepatocyte uptake, they would make useful CT liver contrast agents; in actual practice, however, hepatocyte uptake is too slow and excretion too fast for them to serve this function.

Toxicity and allergic reactions are more severe with iodipamide than with more typical intravascular contrast agents. Nephrotoxicity is dose dependent. In part because of this toxicity, cholangiography has been supplanted by other imaging, including MRI and direct cholangiopancreatography. The latter is achieved by percutaneous transhepatic cholangiography, an endoscopic retrograde approach, or injection through a surgically placed tube.

Direct cholangiography is generally performed with full-strength contrast concentrations (≈ 300 mg iodine/mL). In particular, when searching for subtle leaks, a high iodine concentration is advantageous. Also, when injecting proximal to an obstruction, a high iodine concentration allows for dilution by residual bile. When searching for stones, however, dilution of contrast with an equal volume of water appears useful; subtle stones can be missed in markedly opacified bile ducts. Contrast overinjection during direct cholangiography should be avoided. In the United States, syringe injection is common, but in Europe, a drip infusion technique is more popular. The study should be terminated if the pancreatic duct begins to opacify—acute pancreatitis is a complication of this study. Earlier studies suggested that meglumine salts of ionic contrast agents resulted in less bile duct epithelial damage than corresponding sodium salts; the use of nonionic contrast makes this point moot.

Indications for CT cholangiography have been evolving. CT cholecystography is performed 10 to 12 hours after oral administration of a cholecystographic contrast agent (iopanoic acid). Another approach is slow infusion of a cholangiographic contrast agent, resulting in biliary images superior to those obtained with conventional IV cholangiography. Major intrahepatic ducts are visualized in most individuals. Preliminary evidence has suggested that CT cholangiography is somewhat superior to MR cholangiopancreatography (MRCP) in visualizing small biliary stones. It is not useful in jaundiced patients because insufficient contrast is excreted into bile ducts.

MRCP is a noninvasive imaging technique for visualizing biliary and pancreatic ducts. It has evolved as an alternative to diagnostic endoscopic retrograde cholangiopancreatography (ERCP) and diagnostic percutaneous cholangiography. Two approaches are feasible—an IV contrast-assisted technique and a technique without contrast using heavily T2-weighted images to make nonflowing fluid hyperintense. The former uses primarily hepatobiliary MR agents (see later); contrast-containing

bile is hyperintense on T1-weighted sequences. A limitation of this procedure is that reasonable hepatocyte function is required to accumulate enough biliary contrast to be imaged. The contrast-less technique, often simply called MRCP, has none of these limitations and has become the primary imaging study for visualizing bile ducts.

Magnetic Resonance Imaging Contrast Agents

INTRAVASCULAR AGENTS

The term *contrast agent* has a different meaning in MRI than usually applied to barium sulfate or iodinated agents. MRI contrast agents are not visualized directly; rather, their primary function is to alter water proton relaxation times. These agents have considerable variation in diffusion and renal clearance, thus leading to the use of a specific contrast agent for a specific application. Although MRI contrast agents are more complex and serve a more varied function than CT contrast agents, they are used for the same primary purpose—to improve lesion detection and characterization by increasing contrast tissue signal intensity differences because of different effects on tissue proton relaxation. These differences vary with time and depend on the degree of lesion vascularity. Much current MRI contrast agent research has focused on improving their specificity.

MRI contrast agents are often classified by their metal component. A more useful classification is based on their distribution, with the realization that many agents overlap between categories; many are initially blood pool agents but subsequent distribution depends on their molecular configuration:

1. Conventional gadolinium chelates (extracellular agents)
2. Macrophage-monocytic phagocytic (reticuloendothelial) agents
3. Primarily hepatobiliary agents (intracellular agents)
4. Primarily blood pool agents

All currently available MRI contrast agents shorten tissue T1 and T2 relaxation times. The paramagnetic gadolinium and manganese contrast agents primarily shorten T1 and thus increase signal intensity (enhancement) of normal parenchyma on T1-weighted images. The superparamagnetic iron oxides primarily shorten T2, thus decreasing signal intensity on T2-weighted images and, depending on the sequence used, increase the T1 signal. These metal ions are chelated to other structures, such as DTPA, to reduce their toxicity.

Gadolinium Chelates

The most often used vascular MRI contrast agents are gadolinium chelates. These mostly hydrophilic compounds are chelated to “mask” the toxic gadolinium ion. Their biodistribution and perfusion-related issues are similar to iodine-containing contrast agents. To take full advantage of these MRI contrast agents, dynamic imaging must be performed shortly after contrast injection (arterial to portal venous phases); later, these agents equilibrate with the extracellular space, and lesions become isointense to parenchyma. Liver tumor detection with these agents relies on differences in blood flow between tumor and normal tissue. A more recent application of these agents is in MR angiography (MRA) as a substitute for abdominal digital subtraction angiography (DSA). Image processing allows for the separation of arteries and veins.

At recommended doses, gadolinium chelates have a lower adverse reaction rate than iodinated contrast agents, but anaphylactic reactions and even cardiopulmonary arrest, including fatal ones, do occur. Risk factors for reactions are not well defined but appear to be similar to those for iodine contrast. Unlike iodine-related reactions, gadolinium-related reactions tend to be delayed, at times occurring even 1 hour or more later. These agents are excreted by glomerular filtration and, in the usual doses, nephrotoxicity is uncommon, although nephrogenic systemic fibrosis has been reported in some patients with renal disease.³¹

In patients on hemodialysis, about 80% of gadolinium is dialyzed after the first and essentially all after the fourth dialysis. A normal dose has been used in hemodialysis patients.

Gadolinium agents exhibit poor water relaxivity at higher magnetic fields (>4 T). Undoubtedly, new MRI agents will be developed for use with high field strength magnets.

Reticuloendothelial Agents

Larger superparamagnetic iron oxide (SPIO) particles are taken up by the reticuloendothelial system (RES) and, among other effects, result in decreased liver and spleen parenchymal enhancement on T2-weighted images. Uptake is also present in lymph nodes and bone marrow. Ferumoxides (Endorem, Guerbet, Villepinte, France) is an SPIO agent consisting of a colloidal mixture of ferrous and ferric oxide. Tissues lacking reticuloendothelial (RES) cells, such as metastases, have little or no signal loss and thus appear hyperintense to the resultant hypointense, normal RES-containing liver or spleen parenchyma. Not only are known tumors better identified but, compared with unenhanced MRI sequences, more tumors are detected. This differentiation is not absolute, however, because some well-differentiated neoplasms contain RES cells and thus take up iron oxide particles. These SPIO-induced changes differ among various tumors, potentially providing tissue characterization of different tumors. SPIO enhancement is impaired in diffuse liver disease. Nevertheless, imaging interpretations with these compounds is complex; some of the particles are ultrasmall, and T1-weighted gradient-echo sequences result in imaging patterns similar to those with Gd chelates and ultrasmall SPIO particles.

These agents have a longer intravascular half-life than gadolinium chelates. A prolonged scanning window is available once these particles are within the RES; eventually, free iron is used in normal iron metabolism. Their role in clinical imaging has not yet been clearly defined. Disadvantages include prolonged scanning times and an increased false-positive rate.

Hepatobiliary Agents (Intracellular Agents)

Several hepatobiliary-specific paramagnetic contrast agents, such as Gd-EOB-DTPA (Eovist, Bayer Imaging, Whippany, NJ) and Gd-BOPTA (MultiHance, Bracco Diagnostics) are initially extracellular and then undergo hepatocyte uptake. Early dynamic perfusion imaging is similar to that with conventional gadolinium chelates, but this can be followed by delayed hepatic imaging; each phase yields different information. Image interpretation differs from conventional gadolinium scans; thus, with Gd-BOPTA, a hepatocellular carcinoma shows early peripheral enhancement, but parenchymal phase images reveal an isointense or even hypointense tumor.³²

These agents are eliminated by biliary and renal pathways. Eovist achieves greater liver enhancement than MultiHance, has

a biliary excretion rate of about 50% of the injected dose, and a delayed biliary phase is evident. Gd-BOPTA exhibits a T1 relaxivity roughly double that of conventional gadolinium agents, probably secondary to its binding to albumin, which decreases extravascular leakage. Although only a small percentage is taken up by hepatocytes, this has a prolonged effect on liver signal intensity.

Mn-DPDP (Teslascan, GE Healthcare AS, Buckinghamshire, England) dissociates partly in plasma, with free Mn^{2+} taken up by hepatocytes and other tissues, including the pancreas. Non-dissociated Mn-DPDP is eventually eliminated by the kidneys. It is often considered to be a hepatobiliary-specific paramagnetic contrast agent, having an effect lasting for several hours, thus permitting delayed imaging. It is injected by slow IV infusion, so dynamic imaging is not feasible. On T1-weighted images, this agent selectively enhances normal liver parenchyma and hepatocyte-containing tumors such as focal nodular hyperplasia, regenerative nodules, and hepatocellular adenomas and carcinomas, but shows little or no enhancement of metastases, cysts, and hemangiomas. This agent differentiates hepatocellular carcinomas from metastases, with metastases of nonhepatocyte origin becoming more conspicuous because of an increased signal from surrounding normal liver parenchyma. An exception is metastatic neuroendocrine tumors; occasionally, these tumors enhance with Mn-DPDP. A possible use is during MRI-guided thermal tumor ablation when prolonged tumor visualization is beneficial³³; Mn-DPDP identifies more focal tumors in cirrhotic and noncirrhotic livers than detected on precontrast images. It appears useful in defining intrahepatic biliary anatomic variants, such as in pretransplantation liver lobe donors. Because it does not differentiate between benign and malignant primary liver neoplasms, its diagnostic impact is not clear.

Manganese is excreted in bile, but excretion is inhibited in biliary stasis. It is contraindicated in severe liver failure. Mn-DPDP's overall safety appears to be similar to that of the other hepatocyte gadolinium products.

Blood Pool Agents

Ultrasound superparamagnetic iron oxide (USPIO) particles, unlike most MRI contrast agents, shorten T1 and T2 relaxation times, with a few exceptions. Initially conceived as MRI lymphographic agents, their current role has evolved mostly into blood pool agents. They have a blood half-life measured in hours. One disadvantage is the superimposition of arteries and veins, although image processing techniques such as subtraction and phase contrast can differentiate these structures. These iron oxide contrast agents appear useful in differentiating highly vascular lesions, such as hemangiomas, from solid neoplasms. Also, their prolonged reduction of intravascular T1 values makes them useful for MR angiographic interventional procedures without need for repeat contrast injection. Their relaxivity increases at lower field strengths, and they are therefore suitable for use in open magnets.

Iron oxide particles smaller than 10 nm pass through capillaries and are eventually cleared by liver, spleen, bone marrow, and lymph node reticuloendothelial cells, resulting in homogeneous signal loss in these structures. These agents therefore can potentially identify lymph node metastasis independently of node size; normal nodes lose signal intensity but nodes (or regions of nodes) containing metastases do not take up these particles.³⁴

A potential use for iron oxide agents is to label them with a target-specific drug, such as cholecystokinin, with receptors in the pancreas. Development of such agents is still in its infancy.

A separate group of blood pool contrast agents consists of gadolinium-based products bound to albumin, dextran, or another similarly large molecule (also called macromolecular MRI contrast agents); imaging using Gd-BOPTA has already been discussed (see earlier). Biodegradable polymeric MRI contrast agents have been reported.³⁵ Tight albumin binding prolongs blood pool time. The clinical role of these agents presumably will be similar to that of USPIO agents.

Carbon dioxide is a blood pool MRI contrast agent. An intravascular column of carbon dioxide leads to signal loss and results in a black blood MR angiography technique.

More complex applications of MRI contrast agents involve combining two agents (sometimes called double-contrast MRI imaging). For example, more information is obtained about a focal tumor by combining perfusion data of a gadolinium chelate with its RES status obtained with a SPIO agent than is possible with a single agent alone. Such combined contrast agent use is mostly experimental.

Another research approach involves excitation-based, frequency-labeled, exchange transfer imaging to separate tissue magnetization transfer contrast components by using a paramagnetic chemical exchange saturation transfer agent.³⁶ MRA of hepatic vessels appears comparable to DSA and superior to portal vein images for evaluating liver arteries.

GASTROINTESTINAL AGENTS

An oral MRI bowel contrast agent identifies the bowel lumen and differentiates the normal bowel wall from an abnormal process. Bowel distention can be obtained by injecting contrast via a nasojejunal catheter (enteroclysis) or having the patient drink a large quantity of fluid (enterography). An oral contrast agent aids in identifying a soft tissue tumor in the bowel wall and in adjacent organs.

Oral MRI contrast agents are subdivided into positive contrast agents, which predominantly shorten T1 and increase MRI signal intensity on T1-weighted images, and negative contrast agents, which shorten T2 and decrease signal intensity or simply lack hydrogen protons and water-density contrast. Positive contrast agents consist of various iron, manganese, and gadolinium paramagnetic compounds; they are useful in detecting sinus tracts. On the other hand, they mask intraluminal content and make bowel wall visualization difficult.

A distinction between positive and negative contrast agents is not absolute, and some agents change properties with dilution and the MRI sequence used. Gadolinium is a positive contrast agent that shortens T1 in the small bowel but, when concentrated in the colon, it acts as a negative contrast agent. Ferric ammonium citrate is hyperintense on T1- and T2-weighted images at concentrations lower than 45 mg/mL; at higher concentrations, and at 10 to 20 mg/mL, bowel loops become hypointense on T2-weighted images. A more relevant issue is whether such contrast improves lesion detection; current results are not clear.

A dilute barium sulfate suspension is a useful negative agent. Perfluorocarbons lack hydrogen protons and do not produce an MRI signal on T1- or T2-weighted images, but their role as oral agents is not established. Methylcellulose, polyethylene glycol, and dilute magnesium sulfate³⁷ have been evaluated. Air and

water are also MR contrast agents. Nonabsorbable water-density agents are similar to those used for CT (see earlier).

Positive contrast agents accentuate motion artifacts. However, contrast artifacts are more pronounced with negative agents, but bowel wall abnormalities are better evaluated with negative agents. Antiperistaltic pharmacologic agents have been used; they reduce motion artifacts, even with a high field strength unit.

MR colonography is performed using water, a gadolinium solution, or a barium suspension as a luminal contrast agent. Evaluation can include surface-rendered, virtual endoscopic endoluminal views, orthogonal sections in three planes, and water-sensitive images.³⁸ A preliminary report has suggested that MR proctography is inferior to barium proctography for detecting pelvic floor abnormalities.³⁹

Pharmacoradiology

Pharmacologic agents useful in GI radiology will be discussed in this section. Included are those having an intravascular effect (vasoconstrictors and vasodilators), those modifying gut motility, and those affecting bile flow. Excluded are experimental agents, agents designed for molecular imaging, and therapeutic materials.

From a radiologist's viewpoint, most gut motility agents can be divided into those that increase GI tonicity and motility and those that decrease these functions. Some agents have different effects on different parts of the GI tract; they are discussed separately in the section on mixed action agents.

Bowel tonicity is not the same as peristalsis. In general, however, pharmacologic agents that increase bowel tonicity also result in increased peristalsis. For example, agents inducing gastric hypertonia tend to result in faster gastric emptying and hypertonic small bowel agents result in faster small bowel transit. Hypotonic agents have an opposite effect.

One exception to this classification is famotidine, which suppresses gastric secretions. A preliminary report suggested that famotidine may be useful prior to an upper GI examination; the decreased gastric secretion improved the quality of the examination.⁴⁰

VASOCONSTRICTORS

The primary use of vasoactive drugs in abdominal imaging is to alter blood flow in a way designed to increase diagnostic accuracy. Some drugs aid delivery of chemotherapeutic agents to neoplasms. All side effects must be acceptable. Vasoconstrictors aid primarily in detecting and characterizing neoplasms; they constrict normal blood vessels but have little if any effect on malignant vessels.

Epinephrine, an adrenergic hormone, stimulates α and β receptors and, depending on specific innervation, results in vasoconstriction or dilation. Initially used in renal arteriography, epinephrine decreases contrast opacification of normal renal parenchyma, thus accentuating renal cell carcinoma vasculature. Limitations for the use of epinephrine include a variable dose response and the ability of some inflammatory tissue neovascularity to respond similarly to neoplastic neovascularity. Hepatic and splenic arterial injection results in spasm of these vessels but little constriction of normal hepatic, gastric, duodenal, and pancreatic small vessels. Also, normal mesenteric vessels do not respond appreciably to epinephrine.

Propranolol blocks β -adrenergic vasodilation and, when used in conjunction with epinephrine, results in mesenteric vessel vasoconstriction.

Norepinephrine has α receptor stimulation similar to that of epinephrine but lacks β receptor stimulation. It has been less well studied for imaging use than epinephrine.

Patients with a pheochromocytoma have increased epinephrine or norepinephrine levels after contrast injection; it thus appears prudent to premedicate these patients with α - and β -adrenoceptor antagonists to control symptoms and prevent an adrenergic crisis, although this may not be necessary when using some nonionic contrast agents.

Angiotensin, a hormone family with vasoconstrictive activity, is a potent vasoconstrictor acting on normal vessel smooth muscle. Similar to epinephrine, it tends to enhance visualization of malignant neoplasms by a selective increase in tumor blood flow.

Vasopressin in pharmacologic doses has a pressor effect and constricts normal splanchnic small vessels (including capillaries), thus decreasing portal blood flow. It has little effect on hepatic artery flow. Transcatheter vasopressin infusion controls some GI hemorrhage, keeping in mind that intra-arterial administration may cause mesenteric infarction or small bowel necrosis.

Bombesin, a gut peptide, releases endogenous gastrin, which activates gastric mucosal sensory neurons, which in turn increase gastric mucosal blood flow and thus protect the mucosa against damage. Somatostatin negates this bombesin-induced gastroprotection. Although bombesin is not used in radiology, the somatostatin analogue, octreotide, has been used for therapy of esophageal and gastric variceal bleeding. Gut neuroendocrine tumors also contain somatostatin receptors, and octreotide is useful for diagnosis and palliation of these tumors. It suppresses carcinoid tumor symptoms.

VASODILATORS

Vasodilators increase blood flow in a selective vascular bed. Their effects differ in normal and neoplastic vessels, but vasodilators are less suitable than vasoconstrictors for outlining small neoplasms; increased normal vascularity tends to obscure a small tumor. Occasionally helpful is a high-calorie meal, which accentuates superior mesenteric artery and portal vein blood flow.

Tolazoline, an adrenergic alpha receptor blocking agent and synthetic vasodilator, aids in the angiographic visualization of small vessels. Direct mesenteric artery injection leads to improved venous visualization. Its effect on neoplasm visualization is mixed. Whether tolazoline has a role in intra-arterial provocative mesenteric angiography to identify GI bleeding is not clear. Infusion therapy with tolazoline and heparin has been used to treat nonocclusive mesenteric ischemia.⁴¹ Intra-arterial verapamil and tolazoline appear to be comparable in their vasodilatory efficacy.⁴²

Bradykinin is a nonapeptide, produced from decapeptide kallidin, normally present in blood in an inactive form. Bradykinin is a plasma kinin, potent vasodilator, and one of the mediators of anaphylaxis released from cytotoxic antibody-coated mast cells. Radiographically, bradykinin injected into the superior mesenteric artery improves portal vein visualization.

Acetylcholine, a parasympathetic hormone, is a vasodilator previously used mostly to evaluate renal artery stenosis.

Dopamine, a potent renal artery dilator, is similar to acetylcholine; it has also been studied mostly in renal vessels. Preliminary work has suggested that dopamine decreases contrast-induced nephrotoxicity, but further studies found that it may have a deleterious effect.⁴³

Prostaglandins have variable vascular effects, depending on their chemical composition and specific use. Prostaglandin therapy is used in neonates with cyanotic congenital heart disease. Prostaglandin E1 (PGE1) has a similar effect on splanchnic vasculature as acetylcholine and tolazoline, resulting in increased portal vein blood flow. Thus, superior mesenteric artery injection of PGE1 during CT hepatic arteriography results in increased conspicuity between hepatocellular carcinoma nodules and surrounding parenchyma.⁴⁴ Also, the use of PGE1 during CT hepatic arteriography helps reduce the number of pseudolesions around the gallbladder bed.⁴⁵ Preliminary work has suggested that it may reduce contrast-induced nephropathy, but this is associated with a number of side effects, and its role is not clear. PGF2 α dilates normal colonic vessels but vasoconstricts inflammatory and neoplastic colon vessels.

Persistent, usually asymptomatic, gastric distention, detected on radiographs, is a complication of prostaglandin therapy. Distention usually resolves after cessation of therapy. Superficially, this condition resembles pyloric stenosis, although imaging shows gastric mucosal thickening and distal antral and pyloric elongation, but no muscular wall thickening.

Papaverine is a vasodilator of large and small vessels. Similar to other vasodilators, it improves portal vein visualization during mesenteric angiography. It is not degraded in a single pass through the liver, and repeated injections can lead to systemic hypotension.

Secretin increases pancreatic blood flow. At times, selective venous sampling after intra-arterial secretin injection aids in detecting gastrinomas. IV secretin, however, does not appear reliable enough for detecting chronic pancreatitis or a pancreatic adenocarcinoma.

GASTROINTESTINAL AGENTS THAT PRODUCE HYPOTONIA

Bowel hypotonia is helpful in a number of settings. For example, a spasmolytic agent dilates a segment of spastic colon that otherwise might mimic a benign stricture or malignancy. Similarly, polyps and diverticula in the small bowel can be detected more readily if the bowel is dilated and atonic. Spasmolytic pharmacologic agents can be divided into hormonal agents (e.g., glucagon) and anticholinergic agents. Agents evaluated for use in the GI tract include morphine, propantheline bromide (Pro-Banthine), atropine, and related compounds. With some agents, after initial enthusiasm, recognition of toxicity and undesirable side effects led to their abandonment.

Glucagon

Human glucagon is a single-chain polypeptide containing 29 amino acid residues, with a molecular weight of 3483. It is generated by α cells in the islets of Langerhans. In some species, glucagon is also produced in the stomach; whether any gastric glucagon is produced in humans is controversial. The glucagon amino acid sequence in animals ranges from one similar to that in humans to completely different sequences. Identical amino acid sequences are found in humans, pigs, and cattle; this was once significant, when glucagon was obtained from animal

pancreatic tissue, but became a moot issue when a synthetic product was developed. Injectable glucagon is produced by the expression of recombinant DNA. The chemical structure of this synthetic glucagon is identical to that of human glucagon.

Glucagon is a hormone that has significant metabolic influence on a number of organs. It binds at specific receptor cell membranes in target organs. In the liver, it stimulates glucose output and hepatic ketogenesis. It lyses adipose tissue and leads to a reduction of circulating cholesterol and triglyceride levels. It stimulates insulin release and appears to be involved in liver regeneration, but its full role in the liver is not clear. Glucagon increases blood flow to the kidneys. Specific effects are also present in the adrenal glands and heart. It is metabolized in the liver and kidney. Glucagon is degraded by gastric secretions and therefore is ineffective when given orally.

In smooth muscle, glucagon is a relatively potent spasmolytic agent, and it is this spasmolytic action that accounts for its use in radiology. Pharmacologic doses are used. Smooth muscle in different GI tract segments varies in sensitivity to glucagon (Table 1-1). For example, 0.1 mg IV is sufficient to induce gastroduodenal hypotonia in most adults, but such a small dose is inadequate for colonic hypotonia, for which a dose several times greater is needed.

Intravascular glucagon is also a vasodilator. It improves portal vein visualization during mesenteric arteriography, although it has been replaced by other vasodilators because of its propensity to induce nausea and vomiting at the doses required for vasodilation.

Gastrointestinal Tract. Acute esophageal obstruction caused by food impaction is often related to an underlying stricture or spasm. Spasmolytic drugs have been recommended if spasm is suspected, but in a multicenter, double-blind study of glucagon and diazepam, no significant difference in disimpaction was evident between spasmolytic agents and placebo.⁴⁷ Effervescent agents have also been used to treat esophageal food impaction, with varying success.

The main advantage of glucagon over anticholinergic agents in inducing upper GI tract hypotonicity is its lack of side effects. In the United States, glucagon is generally used to induce hypotonia; in some countries, the anticholinergic agent scopolamine butylbromide (Buscopan) is used more often. One reason for using an anticholinergic agent is the higher cost of glucagon, although the price ratio of glucagon to Buscopan fluctuates considerably worldwide.

Glucagon decreases intragastric and intraduodenal mean pressures. Some studies suggest that barium mucosal coating in

TABLE 1-1 Spasmolytic Effect of Intravenous Glucagon: Average Duration of Atonicity (min)

Location and Response	GLUCAGON DOSE (mg)			
	0.25	0.5	1	2
Stomach	4.9	8.7	10.1	15.1
Duodenal bulb	7.5	10.1	12.5	16.7
Duodenum	7.8	10.1	12.5	16.1
Proximal small bowel	8.3	9.4	13.7	19.7
Distal small bowel	8.6	9.4	14.0	19.7

From Miller RE, Chernish SM, Brunelle RL, et al: Double-blind radiographic study of dose response to intravenous glucagon for hypotonic duodenography. *Radiology* 127:55-59, 1978.

the stomach and duodenum is improved more with anticholinergic agents than with glucagon, the rationale being that anticholinergics also decrease gastric secretions, whereas glucagon has no such effect. In actual practice, Buscopan and glucagon produce essentially equal distention and barium coating of the stomach and duodenum. A more basic question is whether induced gastric and duodenal hypotonia improves the ability to detect lesions. The diagnostic quality with and without glucagon does not appear to differ significantly. Radiologists in the United States tend not use a hypotonic agent during upper GI studies.

In enteroclysis, barium is instilled until a lesion or obstruction is reached, or the terminal ileum is filled. Glucagon is helpful if it is deemed desirable to slow down barium progression, such as when a suspicious region is identified. In general, 0.25 mg IV is sufficient to induce hypotonia, permitting a leisurely study of the region in question.

During a barium enema, glucagon relaxes the ileocecal valve and allows easier barium reflux into the distal small bowel. Thus, if retrograde ileography is being performed for suspected distal ileal disease, it appears reasonable to administer glucagon. Anticholinergics have little effect on the ileocecal valve.

In select patients, a peroral pneumocolon examination allows double-contrast study of the terminal ileum and right colon. Barium is introduced via a conventional oral examination or enteroclysis approach, and air is added through an enema tip. Because glucagon relaxes the ileocecal valve, it may increase the success rate of this examination.

Colon hypotonia is achieved by injecting 2 mg of glucagon intramuscularly. Hypotonia begins within several minutes and lasts about 15 minutes. Hypotonia can also be achieved with 0.25 to 0.5 mg of glucagon IV, although in some patients up to 1.0 mg may be necessary; the onset of hypotonia with an IV injection is almost immediate and lasts approximately 10 minutes. In general, the smaller IV dose is used because of cost considerations. In infants and children, an IV dose of 0.8 to 1.25 µg/kg has been recommended.⁴⁸

Few studies have evaluated whether the use of glucagon results in a more accurate diagnosis, and whether glucagon is injected during a barium enema varies considerably among radiologists. It is more commonly used in hospitalized, older, and ill patients. In some practices, it is injected routinely for double-contrast barium enemas but individualized with single-contrast studies. In an outpatient setting, many radiologists use glucagon when a patient has painful spasm or spasm interfering with the examination, is unable to retain the enema, or has suspected colitis or diverticulitis. Glucagon decreases the extent and severity of colonic spasm during a barium enema and makes patients more comfortable.

Occasionally, colonic spasm persists despite administration of glucagon. It has been my empiric observation that patients with long-standing diabetes have more glucagon-resistant colonic spasm than nondiabetic patients, but the reason for this decreased response in diabetics is not known. Many diabetics already have high blood glucagon levels, although these levels are in the physiologic rather than pharmacologic range. The presence of autonomic neuropathy in some diabetics may be a factor. At times, refilling the colon several minutes later results in a marked decrease of spasm.

Reduction of Intussusception. Because of its spasmolytic effect and tendency to relax the ileocecal valve, it was thought

that glucagon might have a role in ileocolic intussusception reduction. A number of reports described intussusception reduction after the administration of glucagon, but such empiric use does not imply that any eventual reduction can be attributed to glucagon; even a second or third attempt at reduction improves the overall success rate. Controlled studies have found similar success rates for intussusception reduction with and without glucagon.

Current controversy centers not on whether glucagon is useful in intussusception reduction, but whether the contrast agent should be barium, a saline solution, or air, and whether fluoroscopy or sonography is the preferred imaging modality.

Preferred Imaging Modality with Glucagon

In Computed Tomography. In spite of glucagon's diverse effects in the liver, it does not appear to influence hepatic CT enhancement. With older scanners, glucagon and somatostatin were used to decrease motion artifacts. There is little need to induce bowel hypotonia with multidetector scanners, but the ability to maintain bowel distention with a hypotonic agent aids gastric and bowel wall evaluation. Although some studies suggest that glucagon prior to CT colonography does not improve colonic distention,⁴⁹ others find an antispasmodic agent useful in maintaining hypotonia during air insufflation and scanning. Spasm developing during the study can be decreased by the judicious use of glucagon.

In Ultrasonography. Occasionally, bowel atonia is helpful in abdominal ultrasonography. An acoustic window to the biliary tract can sometimes be obtained by filling the stomach with fluid and inducing hypotonia of the surrounding GI structures.

In Magnetic Resonance Imaging. Currently, glucagon is used infrequently in MRI, although it may have a role if oral MRI contrasts agents and bowel distention are used. When evaluating mural and serosal disease, IV glucagon allows better visualization of normal bowel loops and bowel wall thickening.⁵⁰ Glucagon also helps eliminate ghost images of positive contrast-opacified bowel.

Contraindications and Side Effects

A myth persists that glucagon should not be given to diabetic patients. It should be pointed out that glucagon is used to treat hypoglycemic reactions in diabetics. On the other hand, in the setting of hyperglycemia and ketoacidosis, temporary additional glucose level elevation induced by glucagon is of limited importance. The diabetic patient can safely receive glucagon whenever clinically indicated prior to an imaging study.

Side effects of glucagon are less than those with atropine or propantheline. In one study, the side effects with glucagon were similar to those seen with a placebo. The prevalence of nausea and vomiting after injection of glucagon is dose dependent.⁵¹ When given IV, glucagon slowly decreases these reactions.

Because commercially available glucagon has an amino acid residue similar to human glucagon, allergic reactions should not occur, although rare ones have been reported. In these patients, an allergy to the preservative used, rather than to glucagon, should be considered. Glucagon is a naturally occurring polypeptide and, in pure form, should not result in hypersensitivity reactions. Previously, commercial glucagon contained bovine or porcine insulins, protoinsulins, other nonglucagon

protein contaminants, and preservatives, and any of these may be associated with a hypersensitivity reaction. A rash, periorbital edema, erythema multiforme, respiratory distress, and hypotension have been reported. Currently used genetically engineered glucagon should be associated with few anaphylactic reactions.

Contraindications to glucagon include prior sensitivity, suspected pheochromocytoma, or insulinoma. Glucagon can release catecholamines from a pheochromocytoma and result in the sudden onset of life-threatening hypertension. Such hypertension can be countered with the α -adrenergic blocking agent phentolamine mesylate (Regitine). In adults, a dose of 5 mg IV appears useful, although considerable variability exists in treatment requirements. Glucagon can also stimulate insulin release from an insulinoma, resulting in severe hypoglycemia; this condition is treated with glucose.

Anticholinergic Agents

Anticholinergic agents as a group are effective in tissues with receptors supplied by cholinergic postganglionic autonomic nerves. They block the effect of acetylcholine liberated from nerve endings. They reduce GI tract motility, decrease tonicity in the urinary tract, and may also have a hypotonic effect on the bile ducts. These agents also decrease salivary and bronchial secretions, dilate pupils, and increase heart rate, with the duration of action and specific effect on various target organs dependent on the specific compound and dose. Their action on tonicity and motility is similar to glucagon, but, unlike glucagon, they also reduce secretions. Current evidence suggests that the latter effect is insignificant in imaging studies.

Some of these agents have been used in peptic ulcer disease therapy in conjunction with antacids and H₂ receptor antagonists, although these applications have been inconclusive and controversial. They also play a role in the treatment of irritable bowel syndrome and have been used as supplemental therapy in treating biliary and ureteral colic to relax smooth muscle spasm; results here also are inconsistent.

Useful Agents. The most widely known anticholinergic agent is atropine sulfate. It is available in tablets and as a parenteral injectable liquid. Radiologists in North America may still remember the anticholinergic agent propantheline bromide, in vogue in the 1960s and early 1970s as a GI hypotonic agent. Currently, atropine and propantheline have been supplanted by other agents.

In many countries, the short-acting anticholinergic agent scopolamine butylbromide is used, but it is not available in the United States. It is administered IV; the usual dose is 20 mg before an upper GI examination. Its hypotonic effect lasts for 15 to 20 minutes. It does not induce gastroesophageal reflux, nor does it have any significant effect on the visualization of a hiatal hernia. It may be useful with CT and MRI in evaluating suspected gastric cancers.⁵² One study found that it improves colonic distention during CT colonography (compared with controls), and the authors recommended its use.⁵³

Pirenzepine, an antimuscarinic drug, shows promise as a hypotonic agent without the adverse effects of scopolamine.

Although other anticholinergic agents are available, their side effects and longer duration of action limit their application in radiology. For example, scopolamine hydrobromide is available but is not used in radiologic examinations because of its adverse side effects.

Oral hyoscyamine sulfate is a potential hypotonic agent, having actions and contraindications similar to those of atropine and other anticholinergic agents. It appears to provide no benefit when used as pain premedication during a barium enema, although it aids in achieving distention during CT colonography.

Complications. In patients predisposed to glaucoma, increased intraocular pressure induced by anticholinergic drugs may precipitate an acute attack. Although most patients with a history of glaucoma have chronic glaucoma, a patient may have acute angle-closure glaucoma and not be aware of it. Acute glaucoma should be suspected if eye pain or loss of vision develops after administration of an anticholinergic agent. Buscopan use can result in blurred vision.

The effect on the autonomic nervous system can lead to urinary retention. This complication is exacerbated in patients with prostatic hypertrophy or other predisposition to urine retention. Allergic reactions to anticholinergic agents are uncommon.

GASTROINTESTINAL AGENTS THAT INCREASE BOWEL MOTILITY

In some patients, the rate of gastric emptying is increased if the barium volume used is increased. A cold suspension is not only better tolerated but also leads to faster gastric emptying. Faster small bowel transit can be achieved by adding a hyperosmolar product to a barium suspension; a small amount of diatrizoate meglumine (Gastrografin) can be added to an oral barium suspension.

High-osmolality sorbitol added to oral CT contrast will accelerate bowel opacification. Some manufacturers add sorbitol to their barium sulfate products.

Metoclopramide

Metoclopramide is an antiemetic agent and is also useful in treating diabetic gastroparesis. Its primary effects in the GI tract are an increase in gastric peristalsis, pyloric relaxation, and increase in small bowel peristalsis. It has no major effect on the colon. Metoclopramide appears to decrease gastric secretions but has little effect on mucosal barium coating. A typical dose is 10 to 20 mg parenterally or orally. It is a relatively safe drug, although extrapyramidal side effects, such as acute dystonia and tardive dyskinesia, develop occasionally.

Oral metoclopramide reduces small bowel transit time. It can be given shortly before a small bowel study or up to 90 minutes before the procedure. Administered orally before a CT scan, metoclopramide improves opacification of the ileum, right colon, and transverse colon but not the more proximal bowel. Longitudinal contractions and foreshortening of ileal loops tend to elevate the ileum out of the pelvis. Metoclopramide also appears to improve visualization of the pancreas in abdominal sonography, with its primary benefit being decreased gastric and duodenal gas artifacts.

Domperidone

Domperidone, a potent dopamine antagonist, increases gastric emptying and accelerates small bowel transit. Although it decreases small bowel transit time, its effect on the small bowel appears to be less than that with metoclopramide.⁵⁴ It has been used for the treatment of diabetic gastroparesis. Domperidone

may increase serum levels of prolactin in patients with a pituitary prolactin-releasing tumor. It has also been associated with sudden cardiac death.⁵⁵

Cisapride

Cisapride is a prokinetic substance that induces antral contractility, enhances gastric emptying, and promotes small bowel peristalsis. It also enhances lower esophageal sphincter tone and is a relatively potent esophageal motor stimulator. It has been proposed for the treatment of diabetic patients with gastroparesis and as an antigastroesophageal reflux agent. It has had limited application in radiology. Its use has been discontinued in the United States because of associated cardiac arrhythmias and deaths.⁵⁶

Neostigmine

Neostigmine methyl sulfate is a cholinesterase inhibitor that promotes gastric and small bowel peristalsis and leads to faster gastric emptying and shorter small bowel transit time. It promotes peristalsis when activity is depressed by cholinergic stimulation. It is useful in treating colonic pseudo-obstruction (Ogilvie's syndrome),⁵⁷ but is contraindicated with mechanical bowel obstruction and in some settings of adynamic ileus.⁵⁸ It has led to colon perforation.

Erythromycin

Erythromycin, primarily an antibiotic, improves gastric motility and promotes gastric emptying. It is used as an aid in postoperative gastroparesis and for the treatment of diabetic gastroparesis, but has had little application in radiology.

MIXED ACTION AGENTS

Morphine

Some radiologists may undoubtedly remember using morphine sulfate for hypotonic duodenography, a procedure relegated to history. Currently, morphine has a role in nuclear medicine and a possible role in MRCP (see later).

Cholecystokinin

Cholecystokinin, a peptide hormone, has myriad functions; it induces gallbladder contraction and increases bowel peristalsis, resulting in faster small bowel transit. It also regulates pancreatic enzyme secretion, inhibits gastric acid secretion, affects satiety signaling, and acts as a neurotransmitter. It stimulates aldosterone secretion from human adrenocortical cells. From a radiologic viewpoint, cholecystokinin induces simultaneous contraction of the sphincter of Oddi and gallbladder; thus, most of the bile from the gallbladder refluxes into the intrahepatic bile ducts and reenters the gallbladder after hormone infusion stops.

Secretion of cholecystokinin is impaired in celiac disease and bulimia nervosa. Untreated celiacs have low postprandial cholecystokinin levels. It is overexpressed in certain neuroendocrine tumors and in medullary thyroid carcinomas.

Generally, only the COOH-terminal octapeptide of cholecystokinin is used. This fragment is more potent than the entire molecule.

Ceruletide

Ceruletide is a synthetic compound similar to cholecystokinin in its pharmacologic effects—namely, it delays gastric emptying

and induces gallbladder contraction, duodenal hypoperistalsis, and hyperperistalsis of the jejunum, ileum, and colon. It reverses bowel aperistalsis induced by drugs acting on enteric neural or smooth muscle.

In the early 1980s, ceruletide appeared to be a promising agent to increase small bowel peristalsis and thus shorten the duration of a small bowel examination, but radiologists lost interest in this agent; given IV, ceruletide induces nausea, vomiting, and abdominal cramps. For accelerating small bowel transit, a usual dose of 0.25 to 0.3 µg/kg is administered. Whether the shorter small bowel transit time leads to a better small bowel study is debatable; pronounced contractions tend to obscure anatomic detail, particularly in the distal ileum.

Because ceruletide induces gastric hypotonia, it should not be administered prior to significant amounts of barium reaching the jejunum. Such gastric stasis can be overcome by also administering metoclopramide.

DRUGS AFFECTING THE BILIARY TRACT AND PANCREAS

Bile flow into the duodenum is regulated by bile production in the liver and gallbladder tonicity. Agents affecting only the latter are considered in this section.

Inhibition of gallbladder contractions can be achieved by glucagon, atropine, and other cholinergic drugs, somatostatin, some calcium channel antagonists, and several other less studied drugs, keeping in mind that contractions are also inhibited in obesity, diabetes mellitus, celiac disease, and autonomic neuropathy.

Gallbladder contraction is stimulated by cholecystokinin, ceruletide, motilin, prostigmine, erythromycin, and possibly by cisapride and cholestyramine.

Glucagon relaxes the gallbladder. Glucagon also decreases papilla of Vater mean pressures. Currently, little clinical use has been made of these findings. Glucagon is of limited use in percutaneous transhepatic cholangiography or various biliary drainage procedures. In an occasional patient with persistent distal common bile duct narrowing, in the sphincter of Oddi region, glucagon aids in differentiating a tumor, impacted stone, and spasm. In most patients, however, judicious use of fluoroscopy is sufficient.

Glucagon improves bile duct visualization during MRCP.⁵⁹ Because incomplete duct visualization may lead to a repeat study or even an invasive procedure such as ERCP, glucagon is routinely used at some centers. Although earlier studies suggested that glucagon improves the quality of operative cholangiography, a double-blind prospective study found no improvement.⁶⁰ Use of fentanyl during surgery is associated with sphincter of Oddi spasm and, in these patients, glucagon may have a role.

Hypotonic agents are commonly used during ERCP to induce duodenal hypotonia, inhibit contractions of the sphincter of Oddi, and aid ampullary cannulation. In the United States, glucagon is used almost exclusively for this purpose; in other countries, an anticholinergic drug such as scopolamine is used more often.

Neostigmine, together with morphine, has been proposed as a provocative test in hepatobiliary scintigraphy for evaluation of sphincter of Oddi dyskinesia in postcholecystectomy patients.⁶¹

Morphine may have a role in MR cholangiography; IV morphine constricts the sphincter of Oddi, thus distending the biliary and pancreatic ducts.⁶² It may also improve duct visualization in primary sclerosing cholangitis. An interval of 10 to 20 minutes between morphine injection and imaging appears useful.

Cholecystokinin's effect on the gallbladder has been used to increase radiographic contrast during oral cholecystography; it also aids in evaluating gallbladder function. The gallbladder ejection fraction is typically determined with hepatobiliary scintigraphy but less often with ultrasonography; MR cholangiography uses an infusion of cholecystokinin as an alternate method.

A provocative test using a cholecystokinin derivative (Sin-calide) to identify acalculous cholecystitis patients likely to benefit from cholecystectomy has not achieved general clinical acceptance. Cholecystokinin relaxes the sphincter of Oddi and appears to assist in the passage of bile duct stones. On the other hand, a cholecystokinin receptor antagonist provides pain relief in patients with biliary colic.⁶³ Interestingly, cholecystokinin does not induce its usual sphincter of Oddi inhibitory effect after a cholecystectomy. Cholecystokinin is also useful as a diagnostic test of pancreatic function.

Ceruletide has an effect on the gallbladder similar to that of cholecystokinin or a fatty meal.⁶⁴ In patients with recurrent symptoms after cholecystectomy, an ultrasonographically detected increase in extrahepatic bile duct dilation following ceruletide injection suggests sphincter of Oddi dysfunction.

The cholecystokinin-secretin pancreatic exocrine function test is used to detect pancreatic exocrine insufficiency but does not differentiate between chronic pancreatitis and pancreatic carcinoma. MRI can also evaluate pancreatic exocrine function by measuring duodenal filling after stimulation with secretin.⁶⁵ Secretin improves pancreatic duct visualization and aids in detecting abnormalities during MR pancreatography.⁶⁶ Pancreas divisum and other abnormalities are more readily detected after secretin, potentially obviating the need for ERCP. MR pancreatography is best performed within 5 minutes after secretin injection.⁶⁷ Secretin-augmented MR pancreatography and MRI perfusion are useful for detecting graft dysfunction after pancreatic transplantation.⁶⁸

Analysis of duodenal aspirations of pancreatic juice after cholecystokinin-octapeptide stimulation can detect pancreatic insufficiency in patients with chronic pancreatitis. However, the analogous secretin test is more commonly used.

Interpretation
Artifacts

Since the 1980s, advances in cross-sectional imaging and endoscopy have led to a gradual but steady decline in the number of barium studies performed in the United States.^{1,2} Although barium studies no longer reign supreme in the diagnosis of gastrointestinal (GI) disease, single- and double-contrast examinations continue to have a role in modern radiology practice. In general terms, barium studies can demonstrate GI abnormalities in three ways:

1. Mucosal relief views of the collapsed or partially collapsed lumen obtained with a small volume of barium. These views enable visualization of the folds in various portions of the GI tract (Fig. 2-1A). Because the folds contain a submucosal core, these views are particularly useful for showing abnormalities involving the submucosa, such as esophageal varices.
2. Single-contrast views of the filled lumen obtained with a large volume of low-density barium (Fig. 2-1B). These views enable visualization of contour abnormalities, strictures, and large polypoid defects.
3. Double-contrast views obtained after the mucosal surface has been coated with a thin layer of high-density barium and the lumen has been distended with gas (Fig. 2-1C). These views enable visualization of subtle mucosal lesions, such as the early changes of inflammatory bowel disease and early neoplastic lesions.

Although these three types of views are incorporated to varying degrees in both single- and double-contrast examinations, single-contrast studies rely more heavily on diagnostic fluoroscopy, mucosal relief, and barium filling,³ whereas double-contrast studies emphasize the interpretation of double-contrast images supplemented by barium filling and mucosal relief.

In the past, there was considerable controversy about the relative virtues of single-contrast and double-contrast techniques.^{4,5} Currently, however, most authors believe that double-contrast techniques provide superior mucosal detail and allow earlier detection of subtle lesions than single-contrast techniques. As a result, it is generally recommended that double-contrast studies be performed on patients who are young enough and healthy enough to undergo this type of examination. In contrast, single-contrast barium studies are most appropriate in older or debilitated patients who are unable to cooperate for a double-contrast examination.^{6,7}

This chapter discusses the principles for performing and interpreting single- and double-contrast barium studies.⁸ These principles are illustrated with examples drawn from throughout the GI tract.

Single-Contrast Studies

DIAGNOSTIC PRINCIPLES

Depending on the organ examined, single-contrast techniques may include observation of function (e.g., pharyngeal and esophageal motility), compression imaging, full-column distention, mucosal relief views, and limited air-contrast images.⁹⁻¹¹ The use of compression during fluoroscopy is a critical component of the single-contrast examination. Small lesions (e.g., small ulcers, polypoid neoplasms) are often visible only when the barium pool is adequately thinned or displaced by manual compression. The barium suspension must also be adequately diluted if lesions (especially small lesions) are to be detected in the thinned-out barium pool.

Full-column distention of the lumen is ideal for showing strictures, large neoplasms, and lesions projecting tangentially, such as ulcers or diverticula. Full-column views of barium-filled structures in various projections enable depiction of large ulcers and tumors. However, small lesions may be visible on full-column views only when viewed in profile. In such cases, mucosal techniques are required to supplement the barium-filled views.

EQUIPMENT

Fluoroscopic equipment has evolved dramatically with the transition from analogue cassette-based radiography to digital imaging and viewing on picture archiving and communications system (PACS) workstations.¹²⁻¹⁵ Regardless of the imaging technology, single-contrast examinations can be performed with conventional or remote control fluoroscopic units.¹² The ability to obtain optimal compression views is a major prerequisite of any well-designed fluoroscope. Compression can be performed manually or with a variety of hand-held devices on

Figure 2-1 Three types of views for visualizing the gastrointestinal tract, as illustrated in the esophagus.

A. Mucosal relief view. With the esophagus collapsed and coated, the normal longitudinal folds are seen. **B.** Single-contrast view. With the patient continuously drinking barium in the prone position, the barium-filled esophagus is demonstrated. **C.** Double-contrast view. With the patient in the upright position, the smooth, featureless surface of the esophagus is seen.

a conventional unit; alternatively, the plastic cone on the spot image device of the fluoroscope can be used for applying compression.

On remote control equipment, compression is easily performed with a vertical movable device incorporated into the machine, facilitated by the ability to angle the x-ray tube. Remote control units often contain a compression device that allows graded compression and tube angulation with compression. Nevertheless, many radiologists prefer standard fluoroscopic units rather than remote control units because it is generally easier to move, turn, and compress the patient when the fluoroscopist performing the procedure is at the table side.

BARIUM SUSPENSIONS

Numerous barium products are available commercially; a number are formulated for specific purposes, whereas others can be used for a variety of examinations.^{16,17} Barium suspensions for single-contrast studies should be of moderate density (50%-100% w/v) when not diluted. The optimal barium suspension for a particular study depends on the structure being examined and the type of examination being performed. For example, an esophagogram requires a moderately dense barium suspension that provides full-column and mucosal relief imaging; a high-density barium suspension or paste may also be needed for optimal mucosal coating. A similar barium suspension can be used for an upper GI series, in

which compression views, mucosal relief views, and limited double-contrast views are required. A standard peroral small bowel follow-through study can be performed with the same barium suspension used for the upper GI series. A single-contrast enteroclysis study requires a 15% to 20% w/v barium suspension, although somewhat denser solutions have been recommended.^{18,19} Finally, a 15% to 20% w/v barium suspension is used for a single-contrast barium enema, because this is the optimal suspension for obtaining compression views of the colon.

QUALITY CONTROLS

Quality control for single-contrast examinations requires balancing the barium density, kilovoltage, and width of the barium column to achieve adequate translucency of the barium-filled bowel. This permits radiographic penetration of the barium suspension to visualize lesions that might otherwise be obscured by barium in the lumen.^{6,10,11} The visibility of skeletal shadows through the barium column indicates that small filling defects are more likely to be seen, which is particularly important for the detection of colonic polyps.

Another quality control consideration, especially during the barium enema and small bowel follow-through, is the ability to see through overlapping loops of bowel.^{6,20} On barium enemas, a tortuous sigmoid colon may have overlapping loops, even with appropriate compression. Similarly, on small bowel

follow-throughs, overlapping small bowel loops in the pelvis may compromise the fluoroscopist's ability to detect abnormalities in the distal ileum. In such cases, pelvic loops can be better visualized by placing the patient in a prone position while he or she lies on a bolster or inflated balloon to lift these loops superiorly from the pelvis.²¹

ESOPHAGOGRAPHY

Routine single-contrast esophagography includes fluoroscopic observation of the esophagus supplemented by motion recordings, full-column views, and mucosal relief views.^{22,23} Full-column (barium-filled views) and mucosal relief views constitute the single-contrast phase of the examination. Motion recordings can be used to document pharyngeal function and esophageal motility using analog or digital recordings or rapid sequence solid-state recordings built into modern digital fluoroscopes.¹²⁻¹⁵

Depending on the imaging options of the fluoroscopic equipment, full-column technique is performed by obtaining partial or full-length views of the esophagus distended with barium. These views allow detection of esophageal carcinoma (Fig. 2-2) and other abnormalities at the gastroesophageal junction such as hiatal hernias, peptic strictures, and lower esophageal rings.²² Lower esophageal rings are best visualized on prone views of the barium-filled lower esophagus, sometimes supplemented with a solid bolus such as a marshmallow or barium tablet.²²⁻²⁴

Figure 2-2 Annular carcinoma of the midesophagus. The lesion is well shown on the full-column portion of the barium esophagogram.

Full-column images of the esophagus are usually obtained with the patient on the fluoroscopic table in the prone, right anterior oblique position; a bolster may be used to increase intra-abdominal pressure. Esophageal peristalsis is inhibited by rapid swallowing of barium, allowing the esophagus to distend fully. Multiple images of the esophagus should be obtained at all levels; these images may be full-length views of the esophagus or coned-down views at different levels, depending on the imaging options of the fluoroscopic equipment.

Maximal distention of the esophagogastric region is required for optimal detection of hiatal hernias and lower esophageal rings (Fig. 2-3).^{22,24} Rapid ingestion of the barium suspension followed by deep inspiration (or a Valsalva maneuver) promotes distention of the gastroesophageal junction. Careful fluoroscopic observation is required to visualize lesions only seen when this region is optimally distended.

Full-column views are complemented by mucosal relief views of the collapsed esophagus, with coating of the longitudinal folds by the barium suspension.²³ A high-density barium suspension (e.g., that used for a double-contrast upper GI series) is ideal for this purpose. The patient takes one or several swallows of high-density barium to coat the esophageal folds with barium. These mucosal relief views may reveal thickened, irregular folds, small esophageal neoplasms, and reflux or infectious esophagitis (Fig. 2-4). Nevertheless, double-contrast views are better for showing the plaques of *Candida* esophagitis, the small ulcers of herpes esophagitis, and the giant ulcers of cytomegalovirus (CMV) or human immunodeficiency virus (HIV) esophagitis.²⁵

Single-contrast mucosal relief views are also best for detecting esophageal varices.^{23,26} The patient takes several swallows of the barium suspension, which coats the lower esophagus, and is then asked not to swallow to inhibit peristalsis. Intermittent fluoroscopic observation is performed for several minutes to visualize the varices optimally as they become more distended.

Fluoroscopic observation is an integral part of the radiographic evaluation of the esophagus and is usually adequate to assess esophageal function.^{9,23} Motion recording methods greatly aid in evaluating oropharyngeal swallowing disorders because of the rapid events that occur with deglutition, and may also be used to assess esophageal motility. Motion recordings should be obtained while the patient takes multiple discrete swallows of barium, because rapid swallowing causes reflex inhibition of esophageal peristalsis. With the use of single swallows, the single-contrast esophagogram is an excellent technique for evaluating esophageal motility.⁹

UPPER GASTROINTESTINAL SERIES

The single-contrast upper GI series is a complex examination requiring fluoroscopic observation, abdominal compression, and the use of multiple techniques for examining the esophagus, stomach, and duodenum.^{11,27} The study can be performed quickly and is tolerated even by patients who are immobile or unable to cooperate fully.

The examination starts with the table upright. After the patient ingests several swallows of barium, the stomach is compressed with a compression paddle or the cone on the fluoroscope to demonstrate the rugal folds, assess the pliability of the gastric wall, and detect focal areas of rigidity secondary to

Figure 2-3 Hiatal hernia and lower esophageal ring seen only on prone single-contrast esophagogram. **A.** Upright double-contrast view of the esophagus shows no abnormalities. **B.** Prone full-column view of the esophagogastric region in the same patient shows a hiatal hernia (hh) and a widely patent lower esophageal mucosal ring (arrows).

tumor or scarring. If the stomach empties, the barium-filled duodenal bulb can also be examined by compression in the upright position.

The table is then lowered to the horizontal position, and mucosal relief views of the stomach are obtained, first with the patient in a supine position and then after the patient turns into a prone position. These views supplement the upright compression views and can sometimes show small polyps, erosions, or ulcers that are later obscured in the barium-filled stomach (Fig. 2-5).^{4,28,29}

With the patient in the prone, right anterior oblique position, the esophagus is then examined using the same techniques described previously (see earlier, “Esophagography”). The gastric antrum and duodenal bulb usually fill with barium in this position, so prone compression views of the antrum and duodenal bulb should be obtained using an inflatable balloon placed beneath the patient to thin out the barium pool, enabling detection of anterior wall lesions in the antrum and duodenal bulb (Fig. 2-6).²⁷

With the patient in the supine, left posterior oblique position, air in the stomach rises into the gastric antrum and duodenal bulb, so limited double-contrast images of these areas can be obtained (Fig. 2-7). Compression can be used to displace the barium suspension, separate antroduodenal structures, and improve distention with air. The fluoroscopic portion of the examination is completed at this time. Some radiologists may then choose to obtain a standard set of overhead radiographs of the stomach and duodenum with the patient in prone, supine, right anterior oblique, and right lateral positions.

SMALL BOWEL

The small bowel can be examined by single-contrast technique with a small bowel follow-through, enteroclysis, or retrograde study via an ostomy or reflux from the colon.^{18,19,21} A peroral small bowel follow-through may be performed after a single-contrast upper GI series or as a separate study. A large volume (≥ 500 mL) of barium is recommended to promote gastric emptying, accelerate small bowel transit, and optimally distend small bowel loops. Fluoroscopic imaging and compression of all small bowel loops is a critical component of the examination because focal lesions are easily obscured by overlapping loops of small bowel unless compression is applied to separate these loops and ensure an adequate examination.

A small bowel follow-through typically requires a minimum of 500 mL of orally ingested barium, which can be the same product used for a single-contrast upper GI series. Prone overhead or low-magnification digital images of the small intestine are taken at timed intervals (e.g., every 30 minutes) until barium fills the right side of the colon. Depending on the barium product used, transit time through the small bowel is typically 60 to 90 minutes. Fluoroscopic spot imaging with manual compression should be performed at regular intervals during the examination. Compression of all loops and appropriate imaging of the entire small bowel is required to optimize detection of abnormalities (Fig. 2-8). When the barium suspension has reached the colon, compression views of the terminal ileum are obtained (typically with the patient in a supine or left posterior oblique position) for optimal visualization of this region.

Clear delineation of pelvic loops of small bowel, which often overlap, is not always possible, but several maneuvers may be performed to improve visualization of these loops.²¹ First, the patient should be told not to void during the examination because a full bladder elevates pelvic small bowel loops, enabling them to be separated with manual compression. A

Figure 2-4 Reflux esophagitis on mucosal relief view of the esophagus. Mucosal relief view from single-contrast esophagogram shows crenulated, irregular folds in the distal esophagus, suggesting esophagitis. Reflux esophagitis was confirmed at endoscopy.

similar effect may be achieved by instilling air into the rectum. The patient can also be placed in a prone Trendelenburg position with an inflated balloon beneath the lower abdomen and pelvis to displace pelvic small bowel loops superiorly for better visualization of these loops. If a remote control unit is available, the tube can be angulated to further separate these loops (Fig. 2-9).

Enteroclysis

An intubation small bowel study (enteroclysis) may be performed via a tube placed in the duodenum or jejunum.^{19,21,30} Several enteroclysis catheters are available commercially. The patient can be intubated via the mouth or the nose, with each approach having advantages and drawbacks. When single-contrast enteroclysis is performed, jejunal intubation is preferred to prevent duodenogastric reflux and emesis of barium.

Approximately 800 mL of a 15% to 20% w/v barium suspension is placed in an enema bag, which is hung on an adjustable vertical stand or IV pole. A water-soluble contrast agent may be added to stimulate intestinal peristalsis and shorten the length of the examination.^{16,17,21} The barium suspension is allowed to flow through the tube by gravity, and the rate of flow is regulated by adjusting the height of the enema bag. If the barium suspension flows too slowly, adequate distention is not achieved. Conversely, rapid flow rates may cause reflex paralysis of the small intestine, with slow transit and excessive duodenogastric reflux. Initially, the enema bag is placed about 2 feet above the table; the bag can be raised or lowered during the examination to adjust the flow rate for optimal distention of small bowel loops (Fig. 2-10).

The examination is performed under fluoroscopic guidance with the patient in a supine position. Careful compression spot images of all loops of small intestine are obtained under fluoroscopic guidance as bowel segments become fully distended to depict even subtle abnormalities (Fig. 2-11). When the entire small intestine has been opacified, overhead radiographs or low-magnification digital images of the small bowel are obtained; the patient can then be placed in a prone position to aid in separating small bowel loops in the pelvis.

Figure 2-5 Recumbent compression views for detecting lesions in the stomach. **A.** Compression view of the gastric antrum shows antral erosions as multiple tiny nodules containing punctate collections of barium. **B.** In another patient, compression view of the antrum shows several small polyps (P) as filling defects in the barium pool. The findings in **A** and **B** were not well shown on double-contrast views but were confirmed at endoscopy.

Figure 2-6 Prone compression view of the duodenal bulb showing an anterior wall ulcer.

A. Prone view of the duodenal bulb (a balloon paddle compression device was used) shows an anterior wall ulcer (U) with surrounding edema.

B. Supine oblique air-contrast view of the duodenal bulb in the same patient shows a ring shadow (R) because of barium coating the rim of the unfilled anterior wall ulcer crater.

Figure 2-7 Posterior wall duodenal ulcer on air-contrast view of the bulb. Supine oblique air-contrast view of the duodenal bulb with compression shows a small posterior wall ulcer (arrow), emphasizing the importance of obtaining limited double-contrast views as part of a thorough single-contrast upper gastrointestinal examination.

Figure 2-8 Compression spot image of the small bowel showing a Meckel's diverticulum. A peroral small bowel follow-through study was performed in a patient with gastrointestinal bleeding. Compression spot image of the right lower quadrant shows a Meckel's diverticulum (M) as the cause of the patient's bleeding. The diverticulum was removed at surgery.

BARIUM ENEMA

Fluoroscopic observation, careful imaging with graded compression, and knowledge of appropriate technical factors enables detection of a variety of lesions in the barium-filled colon on single-contrast examinations.^{20,31} Although single-contrast barium enemas are less sensitive than double-contrast examinations for detecting small polypoid lesions

and for evaluation of inflammatory bowel disease,^{6,20,32} the single-contrast barium enema can be performed quickly and is usually a better choice for patients who are immobile, older, or incontinent.^{6,7}

Preparation of the large bowel is the most important prerequisite for an accurate single- or double-contrast barium enema.^{4,27} The diagnosis of neoplasms, including small polyps,

Figure 2-9 Peroral small bowel follow-through study in a posthysterectomy patient with pelvic small bowel loops lying deep within the pelvis. A prone image of the pelvis with a bolster placed beneath the patient and x-ray tube angulation clearly shows the cecum (C) and ileocecal junction. Note how pelvic loops of ileum are well separated and visualized.

Figure 2-10 Single-contrast enteroclysis. Normal small bowel loops are well distended, with the folds in a parallel arrangement. The use of a dilute barium suspension permits a see-through effect for visualization of overlapping loops of small bowel.

is easier and more reliable in a well-cleansed colon. Conversely, the presence of stool invariably limits the detection of polyps and is the most common cause of errors when interpreting the images.^{4,31}

A variety of colon-cleansing protocols can be used to obtain a thoroughly clean colon in the vast majority of patients.^{31,33} One recommended bowel preparation regimen includes the following:

1. A 24-hour clear liquid diet
2. One glass of water hourly the day before the examination
3. A saline cathartic such as magnesium citrate at 4:00 PM the day before the examination
4. 60 mL of a flavored castor oil or other irritant cathartic at 8:00 PM the day before the examination
5. An optional 1500-mL tap water cleansing enema the morning of the barium enema examination, although the need for a water enema is controversial³⁴

If a tap water enema is administered, the patient needs to wait at least 30 minutes before the single-contrast barium enema is performed to avoid excess fluid in the colon, which might further dilute the barium suspension and degrade the quality of the study.^{31,33,35}

A thorough examination protocol must be followed to ensure that an adequate single-contrast barium enema is obtained.^{6,20,31} All portions of the colon must be adequately visualized and imaged without overlapping segments to increase the fluoroscopist's confidence that suspected lesions are real

Figure 2-11 Nonobstructing adhesions on single-contrast enteroclysis with compression. Compression view of the mid small bowel shows focal nonobstructing adhesions (arrows) with angulation of the affected bowel and an inability to separate adjacent loops.

(Fig. 2-12). As in the small bowel follow-through, manual compression of the colon is a critical component of the examination because polyps and polypoid cancers protruding into the lumen may only be visualized with adequate thinning of the barium column (Fig. 2-13).^{20,31} Overhead radiographs may be obtained at the end of the examination, followed by a postevacuation radiograph.

The following technique can be used for performing a thorough single-contrast barium enema.³¹ After insertion of the rectal tip, the patient is placed in the left posterior oblique position, the flow of the barium suspension is started slowly, and a spot image of the rectosigmoid region is obtained while distention is minimal. Because the rectum cannot be compressed, this early image allows smaller lesions to be detected more easily. The rectosigmoid region is again imaged when fully distended. An appropriate number of views are obtained to demonstrate the sigmoid colon without overlapping loops. The entire colon is then opacified to the cecum, avoiding ileal reflux, if possible. Compression spot images of the remaining segments of colon are then obtained. After the fluoroscopic examination has been completed, overhead radiographs may be obtained. When using a remote control unit, the overheads may be taken during the fluoroscopic portion of the examination. A reasonable sequence of overheads includes a left lateral view of the rectum, prone and supine views of the colon, supine left and right anterior oblique views of the colon, and a prone angled view of the rectosigmoid.

Figure 2-12 Colonic carcinoma on single-contrast barium enema. This oblique compression spot image of the splenic flexure shows a polypoid, ulcerated carcinoma (arrows) of the distal transverse colon. Careful patient positioning and the use of compression are critical components of this examination.

A postevacuation radiograph is generally obtained at the end of the study to document colonic emptying and rule out gross colonic dysmotility. The postevacuation radiograph may also show that a filling defect seen on earlier barium-filled views persists or disappears, thereby indicating whether this finding was caused by a true polyp or residual stool (Fig. 2-14).

Double-Contrast Studies

PERFORMANCE

The yield of diagnostic information from double-contrast studies can be maximized only with meticulous attention to the technical aspects of the examination. The major principles of performance include mucosal coating, distention, and projection.

Mucosal Coating

The diagnostic quality of double-contrast studies depends on the quality of mucosal coating. In the absence of good coating, lesions can be missed or patchy coating can be mistaken for a lesion. Good mucosal coating requires optimal interaction between the barium suspension and mucosal surface. An appropriate barium suspension must be chosen; it must be prepared properly,³⁶ and the mucosal surface must be clean enough to enable adequate coating. Even when the mucosal coating is only slightly impaired, major abnormalities can be missed (Fig. 2-15).

Figure 2-13 Small colonic polyp on compression spot image from a single-contrast barium enema. Oblique compression spot image of the splenic flexure shows an 8-mm colonic polyp (arrow). This small polyp was not seen on other images of the same area when compression was not applied.

Figure 2-14 Value of postevacuation radiographs for detecting colonic polyps.

A. Compression spot image shows a small (<1 cm) filling defect (arrow) in the descending colon on a single-contrast barium enema. Diverticula are also present in this region. The filling defect was not clearly present on other views. **B.** Postevacuation compression spot image of the descending colon (note the location of the previously seen diverticula) again shows this small filling defect (arrow), indicating that it is a true polyp. A small adenoma was removed at colonoscopy.

Figure 2-15 Risk of suboptimal coating. **A.** On the initial radiograph, an ulcer crater is barely recognizable along the lesser curvature of the stomach. **B.** With additional rotation and improved coating, the large ulcer crater (arrow) is clearly seen.

Distention

Normal folds are soft and pliable and are therefore effaced with moderate distention. The optimal degree of distention is that which just effaces the normal folds. Inadequate distention may conceal lesions, but overdistention can also obscure lesions such as shallow ulcers. Varying degrees of distention may therefore be required for optimal visualization of complex or subtle lesions. Overdistention may accentuate areas of rigidity, whereas partial collapse may accentuate abnormalities of the folds. The final diagnosis represents a synthesis of the information obtained with these various views (Fig. 2-16).

Projection

An adequate number of views should be obtained, so each loop of bowel is projected free of overlapping loops. Ideally, each segment of bowel should also be demonstrated in profile. In practice, however, these goals cannot always be achieved. It is

therefore important to assess overlapping loops of bowel and be able to recognize abnormalities that are viewed en face as well as in profile. This is particularly important for recognition of short, annular lesions in the colon because it may be difficult to demonstrate every colonic bend in profile (Fig. 2-17).

INTERPRETATION

After every effort is made to obtain excellent images, it is important to extract all of the diagnostic information available on these images. The interpretation of double-contrast studies also differs substantially from the interpretation of single-contrast studies.

Dependent and Nondependent Surfaces

The distinction between the dependent and nondependent surfaces must be understood. The nondependent surface has a thin coating of barium because all the free barium falls onto the

Figure 2-16 Adenocarcinoma in Barrett's esophagus. **A.** Double-contrast view shows ulceration and slight rigidity of the contour in the lower esophagus. **B.** Mucosal relief view shows the polypoid nature of the lesion. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 2-17 Annular carcinoma seen en face and in profile. **A.** There is irregularity of the lumen seen end-on (arrow) caused by an annular carcinoma. **B.** The annular lesion is readily apparent when viewed in profile on an appropriate oblique projection. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

dependent surface. As a result, the dependent surface has a thicker coating of barium, and the barium pool accumulates in any depression or concavity. The usual double-contrast image obtained with a vertical beam results in superimposition of the dependent and nondependent surfaces and any barium pool that might be present. The distinction between these surfaces is more clearly demonstrated on horizontal beam radiographs (Fig. 2-18).

Lesions in the GI tract can generally be classified as protruded or depressed, and their appearance depends on whether they are located on dependent or nondependent surfaces. Their appearance can also be affected or even masked by the barium pool.

Protrusions

Protrusions into the lumen of a hollow viscus can be normal structures such as folds or pathologic lesions such as polypoid tumors. The radiographic principles underlying the appearance

Figure 2-18 Dependent and nondependent surfaces. The distinction between the dependent and nondependent surfaces is clearly shown on this horizontal beam radiograph of the colon. The nondependent surface has a thin coating of barium, whereas the dependent surface contains the barium pool.

of protrusions are illustrated in Figure 2-19, which represents a cross-section through the stomach with rugal folds on its anterior and posterior walls. With the patient in the supine position, the posterior wall is dependent and the anterior wall is nondependent.

A protrusion on the dependent surface displaces barium from the barium pool and is therefore seen as a radiolucent filling defect. A protrusion on the nondependent surface is coated with barium, and the x-ray beam catches the edges of the protrusion, which are then etched in white. Figure 2-20 illustrates the different appearances of a lesion when it is located on the dependent surface and then on the nondependent surface.

In general, the density of the etching depends on the thickness of the lesion, so the etching of a slightly protruded or plaque-like lesion may be extremely faint. Such lesions are best demonstrated on the dependent surface in the presence of a shallow barium pool. Flow technique is particularly valuable for detecting these lesions.³⁷

Several other appearances are associated with protruded lesions. The stalactite phenomenon represents a droplet of barium hanging from a protrusion on the nondependent surface (Fig. 2-21).³⁸ These barium droplets can be differentiated from ulcers because they are almost always associated with protrusions on the nondependent surface and disappear as the droplet falls away. Nevertheless, it is important to recognize these stalactites because they may be the only clue to the presence of a protruded lesion on the nondependent surface.³⁹

The so-called bowler hat sign may be seen with a polypoid lesion or diverticulum. With a diverticulum, however, the dome of the hat points outward from the long axis of the bowel (Fig. 2-22A), whereas with a polyp, the dome of the hat points toward the lumen (Fig. 2-22B).⁴⁰ The so-called Mexican hat sign represents a pedunculated polyp hanging from the nondependent surface. The outer ring represents the head of the polyp, and the inner ring represents the stalk seen end-on through the head (Fig. 2-23).

Depressed Lesions

Depressed lesions are lesions such as ulcers or diverticula that extend beyond the normal contour of the bowel. When located

Figure 2-19 Principles underlying the appearance of protrusions. A, B. Diagrammatic representations of the appearance of a rugal fold on the anterior and posterior walls of the stomach. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 2-20 Effect of position on the appearance of a rectal carcinoma. **A.** With the patient in the supine position, there is a lobulated filling defect in the distal rectum. The plaque-like carcinoma is therefore on the dependent (posterior) wall. **B.** With the patient turned into the prone position, the carcinoma is now etched in white because it is on the nondependent (anterior) surface.

Figure 2-21 The stalactite phenomenon. Radiograph of the colon with the patient in the upright position shows a long droplet of barium (arrow) hanging from a haustral fold. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 2-22 Bowler hat: polyp or diverticulum? **A.** When the dome of the hat (arrow) points away from the long axis of the bowel, it is a diverticulum. **B.** When the dome of the hat points toward the lumen of the bowel, it is a polyp. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 2-23 Mexican hat sign. Typical appearance of a pedunculated polyp seen end-on. The outer ring represents the head of the polyp, and the inner ring represents the stalk.

on the dependent surface, they trap barium and are therefore seen as focal barium collections (Fig. 2-24A). Conversely, when located on the nondependent surface, they empty of barium. If there is adequate coating of the sides of a depressed lesion, however, it can be recognized as a ring shadow (Figs. 2-24B and C). In patients with colonic diverticulosis, the appearance of these lesions therefore depends on their location in the bowel; diverticula on the dependent surface tend to fill with barium, whereas diverticula on the nondependent surface usually appear as ring shadows (Fig. 2-25).

This concept is particularly important for the recognition of anterior wall duodenal ulcers. With the patient in the supine or supine left posterior oblique position, the ulcer may be manifested by a ring shadow or crescent because of barium coating the rim of the unfilled, nondependent ulcer crater (see Fig. 2-24B). When the patient is placed in the prone position, however, the ulcer fills with barium (see Fig. 2-24C).

Barium Pool

The barium pool is the “paint” of the radiologic artist. In essence, the double-contrast examination requires manipulation of the barium pool to paint or coat the entire mucosal surface. At the same time, the barium pool may compromise the study in various ways (Fig. 2-26). It can cover over and submerge a lesion on the dependent surface. Even a small barium pool on the dependent surface can also obscure the etching of a lesion on the nondependent surface (Fig. 2-27). Finally, the barium pool in an overlapping loop of bowel can obscure lesions in the loop of interest.

In general terms, lesions on the dependent surface are best demonstrated with an extremely shallow barium pool, whereas recognition of lesions on the nondependent surface requires that the barium pool on the dependent surface be entirely eliminated. These varying requirements can be met by use of

Figure 2-24 Depressed lesions. **A.** Dependent wall ulcer. Radiograph of the stomach in the right posterior oblique projection shows a high ulcer on the lesser curvature. **B.** Anterior wall ulcer. This spot image in the supine left posterior oblique projection shows a ring shadow (arrow) representing the nondependent ulcer crater etched in white on the anterior wall of a deformed duodenal bulb. **C.** With the patient in the prone position, the ring shadow fills with barium (arrow), indicating an anterior wall duodenal ulcer. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 2-25 Depressed lesions on the dependent and nondependent surfaces. In a segment of colonic diverticulosis, diverticula on the dependent surface are filled with barium, whereas diverticula on the nondependent surface are etched in white.

flow technique (Fig. 2-28).³⁷ As the patient is turned under fluoroscopic control, the flow of the barium pool across the dependent surface is observed. In this way, shallow lesions can be demonstrated on the dependent surface and, as the barium pool flows away, lesions can also be seen on the nondependent surface. The concept of flow technique is important for demonstrating subtle lesions and avoiding diagnostic error.

ARTIFACTS

Many of the artifactual appearances associated with double-contrast studies are obvious to the radiologist.⁴¹ These artifacts include findings caused by barium precipitates (Fig. 2-29A), patchy mucosal coating, and extraneous debris. However, some artifacts may be confusing if they closely resemble pathologic states.

In the colon, some barium suspensions may crack or flake, producing an appearance suggestive of inflammatory bowel disease (Fig. 2-29B). In other patients, there may not be enough distention of the lumen to separate the anterior and posterior walls. The area of apposition is manifested by a so-called kissing artifact, which can simulate a mass lesion (Fig. 2-30A). Kissing artifact can also result from extrinsic compression of the lumen, causing the anterior and posterior walls to become apposed (Fig. 2-30B). In such cases, the appropriate projection should be obtained to identify an extrinsic mass compressing the lumen.

Because the air-filled bowel is translucent, structures in front of or behind the bowel may be projected over the lumen, so they simulate lesions arising from the bowel. It is particularly important to recognize the true nature of barium-filled diverticula and calcified structures overlying the bowel and not to mistake them for polypoid or ulcerated lesions (Fig. 2-31). Other double-contrast artifacts are discussed elsewhere in this text in chapters dealing with specific organs.

Figure 2-26 Diagrammatic representation of the hazards of the barium pool. **A.** The barium pool obscures a lesion on the dependent surface. **B.** The barium pool obscures the fine white etching of a lesion on the nondependent surface. **C.** The barium pool in an overlapping loop of bowel can obscure a lesion on the dependent or nondependent surface. (A and B from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 2-27 Barium pool obscuring a lesion on the nondependent surface. **A.** In the frontal projection, a polypoid carcinoma is seen along the right lateral wall of the rectum. **B.** In the left lateral projection, the rectal carcinoma is on the nondependent surface (right lateral wall) of the rectum, so the lesion is obscured by the barium pool on the dependent surface (left lateral wall).

Figure 2-28 Flow technique. There is a 1-cm sessile polyp in the cecum. The appearance of this small protruded lesion varies as barium flows across the dependent surface of the cecum.

Figure 2-29 Double-contrast artifacts. **A.** Barium precipitates are recognized as sharp, dense barium collections on the mucosal surface. **B.** Flaking of the barium suspension simulates inflammatory bowel disease. (**B** from Laufer I: Air contrast studies of the colon in inflammatory bowel disease. *Crit Rev Diagn Imaging* 9:421–447, 1977.)

Figure 2-30 Kissing artifacts. **A.** A kissing artifact is seen near the lesser curvature of the stomach, simulating a polypoid lesion (arrow). **B.** This kissing artifact results from compression of the stomach by the abdominal aorta (straight arrows). The curved arrow indicates calcification in the wall of the aorta.

Figure 2-31 Duodenal diverticulum simulating a gastric ulcer. **A.** Compression radiograph of the stomach shows a large barium collection (arrow) suggestive of a gastric ulcer. **B.** Supine double-contrast radiograph shows that the barium-filled structure is a large diverticulum arising from the fourth portion of the duodenum.

Careful use of descriptive terms aids in the radiologic analysis of perceived abnormalities. By describing the radiographic characteristics of a lesion, a radiologist can localize the lesion to the mucosa, bowel wall, or tissue extrinsic to bowel. This radiographic description, in conjunction with the site and size of the lesion, age of the patient, and clinical history, enables the radiologist to make a specific diagnosis or formulate a graded differential diagnosis of the most likely possibilities. In addition, precise use of descriptive terms enhances communication between the radiologist and clinician. A radiologist should be able to describe an abnormality so that the person reading or listening to the radiographic report can visualize the lesion without looking at the images.

This chapter is a pictorial glossary that visually defines common descriptive terms in gastrointestinal radiology. The terms are divided according to whether they refer to mucosal lesions, wall lesions (i.e., *submucosal*, *intramural*, or *extramucosal*), or extrinsic lesions.

Surface Patterns

VILLOUS PATTERN

The villi of the small intestine are at the radiographic limits of resolution. Some villi may be seen if the mucosa is well coated

and slightly magnified. This villous pattern is manifested as barely perceptible radiolucencies surrounded by barium in the interstices between villi (Fig. 3-1).

RETICULAR PATTERN

The term *reticular* means netlike (Fig. 3-2). This net is formed by barium in the interstices of normal columnar mucosa, such as the *areae gastricae* of the stomach (see Fig. 3-2A), or in the interstices of a mucosal lesion, such as a carpet lesion. The intervening radiolucent mucosa may be round, ovoid, or polygonal. A reticular pattern typically occurs in abnormalities arising in columnar mucosa. For example, a reticular pattern is seen in the columnar metaplasia of Barrett's esophagus or in a colonic urticarial pattern (see Fig. 3-2B).

GRANULARITY

Granularity implies subtle elevation of the mucosal surface seen en face as small radiolucencies in the shallow barium pool or as punctate dots of barium between lucencies (Fig. 3-3). The "granules" are barely perceptible elevations, with indistinct borders, as if salt had been sprinkled on a plate. Granularity implies mucosa elevated by edema, inflammatory exudate, or

tumor. Barium flocculated on an inflamed mucosal surface can mimic a granular mucosa.

NODULARITY

Mucosal nodules are relatively well-circumscribed elevations seen en face as round to ovoid radiolucencies in the barium pool or as small rings etched in white (Fig. 3-4). In profile, nodules are seen as small hemispheric or sharp-edged elevations of the contour. Nodules may arise in the mucosa itself, lamina propria, or adjacent submucosa. If a mucosal nodule involves a bowel fold, especially the rugae of the stomach or valvulae conniventes of the small bowel, the fold is eccentrically enlarged. Submucosal nodules involving a bowel fold, seen en face, symmetrically splay the parallel surfaces of the fold. Mucosal nodularity may be described as fine or coarse. The distinction between fine nodularity and mucosal granularity is somewhat arbitrary, although mucosal nodules are generally larger and more discrete than granules.

SHAGGY

Shaggy describes such severe mucosal disease that it is difficult to distinguish ulcerated mucosa from sloughed epithelium and inflammatory detritus (Fig. 3-5). In profile, the contour is jagged. En face, numerous lines reflect barium filling the interstices between ulcerated mucosa and debris. Shaggy is frequently used to describe the radiographic findings in severe *Candida* esophagitis (see Fig. 3-5) and ulcerative colitis.

Figure 3-1 Villous pattern. This spot radiograph of the duodenal bulb shows multiple tiny radiolucencies surrounded by shallow, barium-filled grooves in a near-reticular pattern (arrow). The lucencies are the villi seen en face.

Figure 3-2 Reticular pattern. **A.** Areae gastricae. In general, columnar mucosa in the gastrointestinal tract is divided into islands of tissue surrounded by shallow grooves. This pattern is best exemplified in the areae gastricae of the stomach. The areae gastricae are seen as well-circumscribed, polygonal radiolucencies surrounded by barium-filled grooves. **B.** Urticarial pattern in the colon. When colonic mucosa is slightly elevated by edema and/or mild inflammation, the colonic surface may assume a reticular pattern. Barium etches sharply polygonal epithelial islands. This has been termed an *urticarial pattern* because it was first described in colonic urticaria. However, any disease that causes mild edema, inflammation, or ischemia of the mucosa may cause the columnar mucosa of the colon to assume an urticarial pattern, including ischemia caused by obstruction or adynamic ileus or inflammation caused by a viral infection. (**B** from Rubesin SE, Saul SH, Laufer I, et al: *Carpet lesions of the colon*. *RadioGraphics* 5:537–552, 1985.)

Figure 3-3 Granularity: ulcerative colitis. Numerous punctate dots of barium lie between radiolucent islands of mucosa (representative area identified by arrow). The splenic flexure has a tubular configuration, and the interhastral folds are absent.

Figure 3-4 Nodularity: squamous cell carcinoma of the epiglottis. The epiglottis is enlarged. The surface of the epiglottis is distorted by numerous small polygonal 1- to 2-mm radiolucent nodules outlined by barium in grooves between the nodules.

Figure 3-5 Shaggy. *Candida* esophagitis. The mucosal contour is markedly irregular or shaggy. Barium appears to be beneath the mucosal surface (arrows). In reality, this barium is trapped between sloughed epithelial debris and the ulcerated mucosa. En face, there are numerous variable-sized plaques.

COBBLESTONING

Transverse and longitudinal fissuring of the mucosal surface with extension of knifelike clefts into the submucosa and muscularis propria results in cobblestoning, typically seen in Crohn's disease (Fig. 3-6). The cobblestones appear as a carpet of nodules on the luminal surface. The cobblestones represent residual tissue between the transverse and longitudinal clefts.

Fold Patterns

The folds in the gastrointestinal (GI) tract are composed of mucosa—epithelium, lamina propria, and muscularis mucosae—and submucosa. When a radiograph demonstrates enlarged or nodular folds, the process therefore involves the mucosal or submucosal layers, or both. A desmoplastic process involving the serosa or adventitia of the bowel or the adjacent mesenteric or omental fat can secondarily pull on the bowel wall so that the smooth mucosal surface is thrown into an abnormal fold pattern.

STRIAE

When a viscus is less than fully distended, transverse striations may be seen perpendicular to the longitudinal axis of the bowel. Examples of this phenomenon include the so-called feline esophagus, gastric striae (Fig. 3-7), and innominate grooves of the colon.

Figure 3-6 Cobblestoning: Crohn's disease involving the small intestine. Multiple round, ovoid, or polygonal radiolucencies are surrounded by barium-filled transverse and longitudinal fissures. This is also termed the *ulceronodular pattern* of Crohn's disease. The cobblestones represent the mildly inflamed residual mucosa and submucosa between the knifelike clefts. Narrowing of the bowel lumen reflects a transmural inflammatory reaction and bowel wall thickening. (From Rubesin SE, Laufer I, Dinsmore B: *Radiologic investigation of inflammatory bowel disease*. In MacDermott RP, Stenson WF [eds]: *Inflammatory Bowel Disease*. New York, Elsevier Science, 1992, pp 453–492.)

Figure 3-7 Gastric striae. Fine, barium-etched striae (arrows) perpendicularly cross the longitudinal axis of a slightly contracted gastric antrum. The striae are probably caused by contraction of the muscularis mucosae and have been described in patients with biopsy specimens showing normal mucosa or antral gastritis.

WEB

A web is a thin band of mucosa (with or without submucosa) that traverses a variable portion of the intestinal lumen. Webs vary from small shelflike lesions to hemispheric bars and circumferential rings (Fig. 3-8). Webs may be normal variants or the sequelae of inflammatory disease.

Figure 3-8 Web in distal esophagus. A thin radiolucent bar (arrows) is etched in white and crosses part of the circumference of the distal esophagus. Distal esophageal webs are usually related to gastroesophageal reflux disease. (A from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

COIL SPRING SIGN

If barium is forced between one loop of bowel intussuscepting into another loop, the barium may coat the mucosal folds of the outer loop. The result is the radiographic appearance of concentric rings of barium said to resemble a coil spring (Fig. 3-9).

RADIATING FOLDS

Folds that radiate to a focal site guide the radiologist's eye toward GI lesions. Radiographic analysis of the radiating folds aids in the differential diagnosis. Smooth folds radiating to a mucosal lesion indicate an active inflammatory process or scarring (Fig. 3-10A). Lobulated, pointed, or clubbed radiating folds indicate the presence of a malignant or severe inflammatory process (Fig. 3-10B).

POLYPOID FOLDS

Enlarged folds with a lobulated contour may appear polypoid (Fig. 3-11). Diseases that cause polypoid folds originate in the mucosa and submucosa and may also produce distinct polyps.

Figure 3-9 Coil spring sign: metastatic melanoma causing intussusception of the small bowel. Barium refluxes in a retrograde direction into the space between the prolapsing loop of the intussusception (intussusceptum) and the outer loop (intussusciens). The parallel folds of the coil spring (large white arrows) are identified. The intussusceptum is seen as a radiolucency (arrowheads) within the intussusciens. The lumen of the intussusceptum is narrow (small white arrows). The lead point of the intussusceptum is a polypoid mass (black arrows).

Figure 3-11 Polypoid folds. Large lobulated folds (arrows) are present along the greater curvature of the stomach. These thickened folds were caused by *Helicobacter pylori* gastritis.

Figure 3-10 Radiating folds. A. Benign gastric ulcer. Smooth straight folds (short arrows) radiate toward the barium-etched rim of the ulcer (long arrow). **B.** Adenocarcinoma of the stomach. Abnormal folds radiate toward the center of the lesion. The folds are club-shaped (c) and nodular (n). Note the nodular mucosa in the center of the ulcer crater.

Figure 3-12 Serpentine (serpiginous) folds: esophageal varices. Smooth-surfaced, enlarged, sinuous radiolucent folds are parallel to the longitudinal axis of the esophagus

SERPENTINE (SERPIGINOUS) FOLDS

Serpentine (snakelike) and serpiginous (from the Latin, meaning “to creep”) folds are sinuous or wavy and are often aligned parallel to the longitudinal axis of the bowel. Serpentine folds are seen in mucosal and submucosal inflammatory or vascular processes (Fig. 3-12), especially varices.

STACK OF COINS APPEARANCE

Smooth, straight, enlarged folds perpendicular to the longitudinal axis of the small bowel resemble a stack of coins (Fig. 3-13). This appearance usually indicates submucosal edema or hemorrhage and, rarely, infiltrating tumor. Causes of submucosal hemorrhage include trauma, ischemia, radiation damage, and a bleeding diathesis caused by anticoagulants, hemophilia, and thrombocytopenic purpura.

TETHERING

Mucosal folds may be pulled toward an extrinsic process, resulting in tethering of the folds (Fig. 3-14).

PLEATING

If an extrinsic desmoplastic process extends into the bowel wall, the overlying mucosa may be thrown into thin folds, termed *pleating* (Fig. 3-15). In the colon, this finding suggests

Figure 3-13 Stack of coins appearance: small bowel ischemia. Enlarged, smooth, straight parallel folds are perpendicular to the longitudinal axis of the jejunum. The folds are said to resemble a stack of coins or picket fence.

endometriosis or intraperitoneal metastases involving the serosal surface.

Protruding Lesions

FILLING DEFECT

A filling defect is a radiolucency in the barium pool caused by displacement of the barium by a protruding lesion (Fig. 3-16).

CONTOUR DEFECT

A contour defect is a disruption of the expected luminal contour by a sessile lesion protruding into the GI lumen (Fig. 3-17). A contour defect is not, in itself, a sign of malignancy. However, because the size of the contour defect is related to the size of the lesion, the larger the contour defect, the greater the likelihood of malignancy.

POLYP

A polyp is a protrusion from a mucous membrane. The term *polyp* is not histologically definitive and does not imply adenomatous (dysplastic) change. In general, the height of a polyp is comparable to its width, but a polyp is relatively tall in comparison to a mucosal plaque. Polyps may be seen as radiolucent filling defects on the dependent surface or may be etched in white on the nondependent surface

Figure 3-14 Tethering of mucosal folds: postoperative adhesions involving the pelvic ileum. Smooth mucosal folds (*short arrows*) are no longer perpendicular to the longitudinal axis of the ileum. The bowel is abruptly angulated at the site of adhesion (*long arrow*), and the lumen distal to the partially obstructive adhesion is narrowed.

Figure 3-15 Pleating of the mucosa: endometriosis involving the rectosigmoid junction. The colonic mucosa is thrown into sinuous folds (*arrow*) by a desmoplastic process in the serosa and muscular layers.

Figure 3-16 Filling defect. A. Hyperplastic polyp in the gastric antrum. A filling defect (*arrow*) is seen in the barium pool. **B.** The same polyp is seen in air contrast as a round, increased radiodensity etched in white (*arrow*). In **B**, the polyp is not described as a filling defect.

Figure 3-17 Contour defect: metastatic melanoma in the small intestine. A contour defect (white arrow) is seen as loss of the expected normal contour of the bowel. The contour of the lumen is pushed toward the center of the bowel loop. In this case, a submucosal metastasis is seen in profile (black arrows). Other metastases are seen en face as smooth-surfaced, ovoid filling defects (open arrows) in the barium pool.

(Fig. 3-18). They have many shapes and many radiographic appearances, depending on whether they are small or large, sessile or pedunculated, and smooth or nodular (see Fig. 3-18).

PLAQUE

A plaque is a shallow surface elevation, much broader than it is high. Plaques are so distinct that their margins are etched in white by barium trapped at the interface of the edges of the plaque and adjacent mucosa (Fig. 3-19). Plaques may vary greatly in size, from the small plaques of *Candida* esophagitis to plaque-like tumors.

CARPET LESION

Carpet lesions are focal, flat, well-circumscribed surface elevations. En face, the margin of the lesion is etched in white by barium (Fig. 3-20). When barium fills the interstices of the lesion, multiple small, polygonal radiolucent filling defects are seen surrounded by barium. In profile, the contour may be finely spiculated or nodular. The most characteristic carpet lesions are flat colonic adenomas.

ULCERATED MASS

Lesions that have both depressed and elevated components are typically ulcerated masses of mucosal or submucosal origin (Fig. 3-21).

ANNULAR LESION

Lesions that extend circumferentially around the bowel lumen are termed *annular lesions*. Circumferential spread around the lumen implies that the neoplastic or inflammatory process has spread at least into the submucosa. Annular configurations are seen in benign strictures caused by ischemia, radiation therapy, or diverticulitis or in malignancies such as primary tumors or metastases (Fig. 3-22).

SUBMUCOSAL MASS

The term *submucosal mass* refers to lesions arising in the submucosa and muscularis propria. These are typically benign or malignant tumors of smooth muscle, fat, or neural origin. Because the lesions arise in the submucosa or muscularis propria, they have also been referred to as intramural or extramucosal. The overlying mucosa is stretched and may be ulcerated.

In profile, a smooth-surfaced mass is seen forming right angles to the luminal contour (Fig. 3-23). En face, barium trapped in the abrupt margins results in a well-defined tumor. Central ulcers are seen in about 50% of all submucosal masses (see Fig. 3-24). Small submucosal masses involving a fold symmetrically splay the edges of the fold. Although the radiographic findings are distinctive for large lesions, small (0.5-2.0 cm) submucosal masses may be difficult to distinguish from mucosal polyps.

TARGET LESION

A target lesion or bull's-eye lesion is a mass with a central ulcer crater (Fig. 3-24). Target lesions are typically ulcerated submucosal masses caused by primary tumors such as GI stromal tumors or malignant tumors, especially metastatic melanoma, Kaposi's sarcoma, and disseminated lymphoma.

PLIABILITY

Change or lack of change in the size and shape of a lesion is a clue to its composition (Fig. 3-25). Lesions that change in size or shape, depending on the amount of luminal distention or manual compression, are often composed of fat, fluid, or blood.

Depressed Lesions

EROSION

An erosion is a defect in the mucosa that does not extend beneath the muscularis mucosae. Erosions are characterized by a small central barium collection and a surrounding radiolucent mound of edema (Fig. 3-26). The radiographic appearance is similar to that of aphthoid ulcers seen throughout the GI tract. In some cases, there is no known cause for erosive gastritis, but in most patients, the condition is caused by ingestion of aspirin or other nonsteroidal anti-inflammatory drugs (NSAIDs), viral infection, or alcohol ingestion.

APHTHOID ULCER

An aphthoid ulcer is a small ulcer occurring on a mucous membrane. This is a nonspecific pathologic term derived from the

Figure 3-18 Polyp. **A.** Bowler hat polyp. Barium may be trapped between the edge of the polyp and intestinal lumen as the polyp is pulled against the adjacent wall by its stalk. If the surface and edge of the polyp are at the proper radiographic angle, the polyp appears similar to an English bowler hat. The ring (black arrows) of the polyp is the junction of the polyp and mucosal surface. The dome (white arrow) of the polyp points toward the longitudinal axis of the lumen. **B.** Pedunculated polyp. When a pedunculated polyp is seen in profile, the pedicle of the polyp appears as parallel barium-etched lines (black arrows) or as a tubular radiolucency in the barium pool. The head of the polyp (white arrows) is seen as a round or ovoid filling defect in the barium pool or is etched in white. **C.** Mexican hat polyp. If a pedunculated polyp is seen en face, the pedicle appears as a ring shadow (long arrow) central to the larger ring shadow of the head of the polyp (short arrows). These concentric ring shadows have been termed the *sombrero* or *Mexican hat* sign. **D.** Filiform polyp. A filiform polyp is a tubular or branched polyp, often with a clubbed head. Filiform polyps imply that there has been prior inflammatory disease involving the mucosal surface of the bowel. When residual inflamed, hyperplastic, or reparative tissue protrudes into the lumen, the resulting projections appear filiform. In this patient with quiescent Crohn's disease, numerous filiform polyps (arrows) are seen in the splenic flexure of the colon. (A from Miller WT, Levine MS, Rubesin SE, et al: Bowler-hat sign: A simple principle for differentiating polyps from diverticula. *Radiology* 173:615–617, 1989.)

Figure 3-19 Plaque. *Candida* esophagitis. Small, well-circumscribed radioluencies in the shallow barium pool (arrows) are aligned longitudinally along the esophageal mucosa. Note the normal intervening esophageal mucosa.

Figure 3-20 Carpet lesion: tubulovillous adenoma with carcinoma. A focal reticular network of barium lines crosses the lumen of the ascending colon (thin arrows). The contour of the colon is relatively maintained in one region (open arrow). In an area in which carcinoma is present, the contour is indented and angulated (thick arrows).

Figure 3-21 Ulcerated mass: adenocarcinoma involving the greater curvature of the stomach. A single-contrast compression view of the lesser curvature performed with the patient in a prone position shows an ulcerated mass as an ovoid barium collection (white arrow) within a radiolucent mass protruding into the gastric lumen. The mass has a coarsely nodular rim of tissue (black arrows).

Figure 3-22 Annular lesion: adenocarcinoma of the mid small intestine. A focal annular lesion with abrupt shelflike margins (short arrows) and lobulated folds centrally is seen. The large amount of luminal narrowing (double-ended arrow) means that the tumor has spread at least into the muscularis propria.

Figure 3-23 Submucosal mass: lipoma of the small intestine. A smooth-surfaced polypoid mass (black arrow) projects into the lumen of the mid small bowel. Note the abrupt angulation (white arrows) of the tumor margins and adjacent normal mucosa.

Figure 3-24 Target lesion: metastatic melanoma involving the ileum. Numerous ovoid, well-circumscribed or hemisphere-shaped radiolucent filling defects are seen in the intestine. Several lesions have large, irregularly shaped central barium collections (arrows). These lesions are said to resemble targets or bull's eyes.

Figure 3-25 Pliability. A. Lipoma of the colon. A pear-shaped, smooth-surfaced filling defect (arrows) is seen in the barium column. **B.** A postevacuation radiograph shows that the polypoid mass has elongated (arrows) to conform to the collapsed lumen. These are classic findings of a colonic lipoma.

Figure 3-26 Erosions. Numerous linear and ovoid collections of barium (arrows) are surrounded by radiolucent halos of edema. This erosive gastritis was caused by aspirin use.

Greek root *aphthai* (meaning “to set on fire” or “to inflame”) and originally referred to the oral lesions of thrush, which are raised white plaques. The term was later used by the Greeks to refer to small ulcers on mucous membranes of the mouth (canker sores). Aphthoid means “resembling aphthae”; aphthous means “related to aphthae.” Radiologists use the terms *aphthoid ulcer* and *aphthous ulcer* interchangeably, but the preferred term is *aphthoid ulcer*. The most common causes of aphthoid ulcers are Crohn’s disease, viral infections, varioliform erosions, and amebiasis (Fig. 3-27). Erosions related to NSAIDs may appear identical to aphthoid ulcers.

ULCER NICHE (CRATER)

The term *niche* or *crater* refers to the defect or hole in the mucosal surface, representing an ulcer. The niche may be visualized in profile as a projection of barium extending beyond the luminal contour. Alternatively, the niche may be seen en face as a barium collection, or the edges of the crater may be etched in white (Fig. 3-28).

COLLAR BUTTON ULCER

Collar button ulcers are ulcers with a narrow neck and broad base (Fig. 3-29). These ulcers are formed when the inflammatory process spreads in the soft fat of the lamina propria and submucosa, parallel to the mucosal surface. This lateral extension gives the ulcer a relatively broad base in the submucosa and a narrow neck as it passes through the mucosa. In the colon, common causes of collar button ulcers are amebiasis, ulcerative colitis, and Crohn’s disease.

EXOENTERIC MASS

Exoenteric masses are masses of gastrointestinal origin that extend predominantly outside the bowel rather than into the

Figure 3-27 Aphthoid ulcers: Crohn’s disease involving the splenic flexure of the colon. Numerous aphthoid ulcers are seen en face as punctate barium collections surrounded by radiolucent halos of edema (white arrows). In profile, small ulcers are seen within edematous mounds of mucosa (open arrows).

Figure 3-28 Ulcer niche (crater): benign gastric ulcer. The ulcer niche (crater) is seen as a focal barium collection (arrow). The benign nature of the lesion is indicated by smooth folds that radiate to the ulcer’s margin and lack of surrounding mass effect or mucosal nodularity.

Figure 3-29 Collar button ulcers: spectrum of inflammatory changes in ulcerative colitis. In the proximal transverse colon (T), there is relatively smooth mucosa. This progresses to a granular pattern (G). Distally, there is superficial ulceration (U). When the superficial ulcers penetrate the mucosa, lateral spread of inflammation in the submucosa results in collar button ulcers (arrows). (From Rubesin SE, Laufer I, Dinsmore B: *Radiologic investigation of inflammatory bowel disease*. In MacDermott RP, Stenson WF, [eds]: *Inflammatory Bowel Disease*. New York, Elsevier Science, 1992, pp 453–492.)

lumen of the bowel. They often extend into the mesentery or omentum. These lesions may cavitate, with the cavity extending outside the expected contour of the bowel (Fig. 3-30). The most common neoplastic masses include lymphoma, metastatic melanoma, and GI stromal tumors.

TRACKING

Linear collections of contrast medium within the bowel wall are termed *intramural tracks*. Linear collections of contrast medium outside the expected confines of the bowel are referred to as *extramural tracks*. Intramural tracks frequently course perpendicular to the longitudinal axis of the bowel (Fig. 3-31). Extramural tracks caused by diverticulitis often spread longitudinally in the pericolic fat. Tracks associated with radiation damage, trauma, Crohn's disease, or iatrogenic perforation may spread in any direction.

Contour Abnormalities

TAPERING

A shallow, smooth-surfaced, gradual narrowing of the contour of the bowel reflects a desmoplastic disease in the mucosa and submucosa that tapers the lumen. Tapering is usually caused by benign scarring from chronic inflammatory disease (Fig. 3-32). Occasionally, a neoplasm infiltrating the submucosa may incite a desmoplastic reaction that causes tapering.

Figure 3-30 Exoenteric mass: primary lymphoma of the small intestine. A large barium-filled excavation (thick white arrow) projects from the mesenteric border of the small bowel. Note other radiographic findings of primary small bowel lymphoma, including thickened nodular folds (thin white arrows) and mucosal nodularity (black arrow).

Figure 3-31 Tracking. Crohn's disease involving the descending colon. Numerous intramural tracks (white arrows) extend from the colonic lumen into the pericolic space. The intramural tracks course perpendicular to the lumen through the muscularis propria. A large, linear, extramural barium collection (extramural track; open arrows) lies in the pericolic fat parallel to the lumen.

Figure 3-32 Tapering: benign radiation-induced stricture in the lower esophagus. A long, mild circumferential narrowing of the distal esophagus has a smooth tapered contour (*small arrows*) and smooth mucosa.

LINITIS PLASTICA

The term *linitis plastica* refers to diffuse narrowing and loss of pliability of a GI organ. The linitis pattern is usually seen in scirrhous carcinoma of the stomach ([Fig. 3-33](#)). This type of cancer is also seen in the colon, especially in patients with chronic ulcerative colitis. Both inflammatory and neoplastic processes, however, can result in a linitis appearance. For example, linitis plastica of the stomach may be caused by caustic ingestion or metastatic breast carcinoma. Because these infiltrative processes are primarily in a submucosal location, endoscopic biopsy specimens and brushings may be negative.

THUMBPRINTING

Submucosal hemorrhage or severe edema occurs to a greater degree along the mesenteric border of the small bowel and is manifested radiographically by what is termed *thumbprinting* ([Fig. 3-34](#)).

SACCULATION

Sacculation refers to broad-based outpouchings of the bowel wall. A relatively normal bowel wall may appear sacculated between folds radiating toward a neoplastic or desmoplastic process. This form of sacculation occurs on the bowel wall opposite the mesenteric changes of Crohn's disease ([Fig. 3-35A](#)), ischemia, or diverticulitis. These sacculations do not extend

Figure 3-33 Linitis plastica: adenocarcinoma of the stomach. The fundus and body of the stomach are diffusely narrowed. The luminal contour is altered by nodular, broad-based indentations (*arrows*), but the mucosa is relatively smooth. These findings indicate the submucosal location of the bulk of the infiltrating tumor.

Figure 3-34 Thumbprinting. Polypoid projections (*open arrows*) are seen along the mesenteric border of the ileum. Note the abrupt angulation of the protrusions and smooth surfaces, radiographic findings typical of submucosal lesions. This thumbprinting reflects submucosal hemorrhage in a patient with small bowel vasculitis. Also note the smooth, straight, parallel folds (*long white arrows*)—stack of coins appearance—and interspace spikes (*short white arrow*).

Figure 3-35 Sacculations. **A.** Crohn's disease involving the terminal ileum. The ileal contour is sacculated (black arrows) opposite a longitudinal ulcer (white arrows) on the mesenteric border. Note folds radiating toward the mesenteric border ulcer. Also note a reticular or granular mucosa (open arrows), reflecting mild mucosal changes. **B.** Scleroderma involving the small intestine. Large broad-based sacculations (arrowheads) protrude from the expected contour of the mesenteric border of the small bowel. (**A** courtesy Henrik DeGryse, MD, Antwerp, Belgium.)

Figure 3-36 Spiculation: omental metastases from breast carcinoma infiltrating the serosa of the transverse colon. The superior border of the transverse colon is spiculated (arrows).

Figure 3-37 Angulation of bowel loops: adhesions involving the pelvic ileum. The small bowel is abruptly angulated (arrows) in several locations. Note narrowing of the lumen distal to the obstruction (n) and dilation of the lumen (D) proximal to the angulation. The mucosa is intact.

beyond the expected contour of the bowel. A bowel wall weakened by atrophy or fibrosis of the muscularis propria may also appear sacculated, especially in scleroderma (Fig. 3-35B). Saccululation related to weakening extends beyond the usual contour of the bowel.

SPICULATION

A desmoplastic process extrinsic to the bowel, resulting from inflammatory or neoplastic disease, may extend into the serosa

or muscularis propria and pull the luminal contour into spike-like points, termed *spiculation* (Fig. 3-36).

ANGULATION

Gross angulation of the bowel may occur when an extrinsic desmoplastic process tethers the bowel wall (Fig. 3-37).

Strategic Place for Ultrasound in Bowel Imaging

Transabdominal ultrasound (TAUS) allows the hollow viscera to be identified and characterized by anatomic location, morphology, and mesenteric attachments. At higher frequencies, TAUS and endoluminal probes resolve the bowel wall into multiple concentric layers approximating to the histologic strata¹ and usefully referred to as the sonographic gut signature.

This real-time capability, with patient interaction, to correlate symptoms, clinical signs, and imaging findings, makes TAUS a powerful diagnostic tool. Since the 1970s, the TAUS features of a broad range of common and uncommon gastrointestinal pathologic conditions have been documented in numerous original publications and review articles.²⁻⁴

Ultrasound Features of the Normal Bowel

At higher frequencies (5-17 MHz), the gut signature is comprised of five alternating bands of higher and lower echogenicity equating to serosa (bright), muscularis propria (very dark), submucosa (bright), deep mucosa (dark), and superficial mucosa-lumen interface (bright) (Fig. 4-1). The outer and inner bright bands are very fine and may not be visualized.

Healthy bowel wall is thin (<3 mm), varying with the state of contraction or distention. The muscle layer is the thickest and may be used as a yardstick for assessing relative changes in the mucosa and submucosa.

Ultrasound Findings of the Abnormal Bowel

BOWEL THICKENING

Thickening of the bowel wall is the most commonly identified pathologic feature. With improving technology, the threshold used to assess pathologic thickening has been lowered, from 5 to 3 mm. As the threshold is lowered, sensitivity increases at the cost of specificity.

Thickening may be caused by the presence of edema, hemorrhage, inflammation, tumor growth, or infiltration. Any of these may result in the classic ultrasound (US) feature of a hypoechoic circumferential thickening around a strong echogenic center (lumen), variously referred to as the target sign, ring sign, or pseudokidney sign (Fig. 4-2).

For more specific diagnostic indicators, thickened bowel must be characterized as focal or diffuse, circumferential or segmental, and solitary or multifocal. Tumors may grow into the bowel lumen to produce a polyp or polypoid mass (Fig. 4-3A) or away from the lumen into the peritoneal cavity (see Fig. 4-3B).

BOWEL WALL LAYERS

Changes in the gut signature within and adjacent to an observed bowel lesion should be carefully assessed. The high resolution of US provides a unique opportunity to identify the specific bowel layers affected, characterize the lesions, and diagnose the underlying process.

In pathologic conditions, the gut signature may be preserved, exaggerated, distorted, diminished, or obliterated. Focal alterations of the gut signature may allow identification of bowel lesions with borderline thickening (Fig. 4-4).

BOWEL LUMEN

Commonly, when the bowel wall is thickened, the bowel lumen is compromised, becoming narrowed or strictured. An uncommon exception to this is the aneurysmal dilation seen in lymphomas and gastrointestinal stromal tumors (GISTs), in which the lumen in the diseased segment enlarges.

Dilation of the bowel lumen is seen proximal to an obstructing lesion, where it is initially accompanied by increased peristalsis. Dilation with no peristalsis may be caused by late-stage obstruction or paralytic ileus, usually seen after abdominal surgery.

BOWEL PLASTICITY, MOBILITY, AND PERISTALSIS

TAUS resolution permits visualization of peristalsing small bowel folds, particularly as fluid passes along the lumen (Fig. 4-5A), and of rigid folds in dilated, fluid-filled obstructed loops

(Fig. 4-5B). Most disease processes result in stiffening of the affected bowel segment, which is observed sonographically as more rigid, less compressible, less easily displaced, and with reduced or absent peristalsis. Real-time scanning allows for the observation of other motility disorders, such as nonobstructive intussusceptions in celiac disease (Fig. 4-6).

ALTERED BLOOD FLOW

Doppler signals are negligible in normal bowel wall but assessment of flow in masses or thickened segments is essential. Color and power Doppler signals indicate hyperemia in actively inflamed segments or hypervascular lesions, and the absence of signals in a conspicuously thickened bowel segment may indicate ischemia. Most tumors have sparse Doppler signals but hypervascularity is a significant differentiator and should be routinely assessed (see Fig. 4-3B).

EXTRAMURAL AND MESENTERIC CHANGES

Bowel wall disease may extend to involve peri-intestinal structures, adjacent loops, or solid organs. Around inflammatory

Figure 4-1 Sonographic gut signature. Shown is a compressed colon in the left iliac fossa between the rectus muscle (R), psoas muscle (P), and iliac artery (IA). *Inset*, Bowel wall detail of hypoechoic muscle proper (mp), echogenic submucosa (sm), and hypoechoic mucosa (m) between fine bright lines of serosa and mucosa (broken arrows).

Figure 4-2 Pseudokidney and target signs. Inflammatory, neoplastic, and vascular diseases may all cause circumferential bowel thickening, with loss of gut signature, producing a low-echo wall around an echogenic center. This can result in the pseudokidney sign (A), a right colon cancer with acoustic shadowing from gas in the compressed lumen (arrow), or the target sign (B), acute ileitis with transmural inflammation.

Figure 4-3 Focal masses. A. Distal esophageal polyp cancer with intact bowel signature (arrow). B. Bulky, intraperitoneal, dumbbell hypervascular GIST arising from small bowel (arrows). EUS, Endoscopic ultrasound.

Figure 4-4 Altered gut signature—small bowel Crohn's disease. This axial image of a minimally thickened bowel shows blurring of identifiable layers (arrow), with focal signature obliteration (*) in the zone of transmurinal inflammation and with exudate on the serosal surface.

bowel lesions, collections, and abscesses, mesenteric fat becomes edematous (swollen and hyperechoic), displacing adjacent structures and increasing the conspicuity of the lesion (Fig. 4-7).

Changes in mesenteric lymph node size, shape (oval, round), echotexture, and surface should be documented. The initial identification of focal mesenteric lymphadenopathy should direct the search for a bowel abnormality.

Ultrasound Technique

TAUS is a well-tolerated, noninvasive technique. A 6-hour fast induces a quiescent intestinal state and reduces bowel gas; no other preparation is required. Focused bowel TAUS is preceded by a general examination of the abdomen and pelvis. Particular attention should be given to deeper recesses inaccessible to the higher frequency probes used for detailed investigation of the bowel wall.

Most bowel pathologic findings displace bowel gas and feces, making them stand out against normal bowel segments. Focal bowel masses, segments of wall thickening, or dilated loops may be apparent, even at lower frequencies, but high-frequency probes are essential to characterize changes in the layers of the bowel wall.

Figure 4-5 Small bowel folds. Valvulae conniventes are depicted (arrows) in the peristalsing jejunum (A) and in a patient with small bowel obstruction (B).

Figure 4-6 Abnormal motility. Spontaneous, nonobstructing, small bowel intussusception is demonstrated in a patient with celiac disease. Shown are axial (A) and longitudinal (B) images, with invaginated small bowel (I) and accompanying bright crescent of mesentery (solid arrows) within an outer bowel sleeve. Bright air bubbles are trapped between the outer layers (broken arrow).

Figure 4-7 Extraintestinal changes. This axial image is of an inflamed appendix, with focal perforation (P) surrounded by edematous echogenic fat (arrows).

GRADED COMPRESSION

The term *graded compression* was introduced by Puylaert to describe the gradual progressive increase in pressure that the operator applies to the probe while making gentle sweeping movements.⁵ Done carefully to minimize discomfort, this is an essential technique for bringing the probe closer to the bowel, displacing bowel gas and overlying bowel loops and assessing the compressibility and rigidity of normal and abnormal bowel loops and mesenteric fat.

Mowing the Lawn

Surveying the entire intestine within the abdominal cavity requires a systematic technique. Puylaert recommended the use of overlapping vertical sweeps of a high-frequency probe up and down the abdomen, similar to the motion of a lawnmower.³ Additional operator techniques include posterior manual compression and scanning in the left lateral decubitus position to assess the retrocecal area.⁶

It is my practice to begin bowel scanning in the left iliac fossa (LIF), where the left colon is easily identified and compressed against the left psoas (see Fig. 4-1). This is an opportunity to optimize scanning parameters so that wall layers can be clearly identified, even in briskly peristalsing small bowel segments.

The distribution of bowel in the right iliac fossa (RIF) is variable. Several small bowel loops may be present, and the terminal ileum should only confidently be identified if continuity with the ileocecal valve is demonstrated. Reexamining the right iliac fossa with the patient in a left decubitus position allows movement of the mobile small bowel and cecum into different positions, redistribution of bowel gas, and improved access to a retrocecal appendix.

In adult female patients, transvaginal scanning may give excellent views of low pelvic bowel loops (Fig. 4-8).

Figure 4-8 Normal appendix. Axial sections along the appendix (arrows) in the RIF lie coiled between the rectus (R) and psoas (P) beneath a loop of normal small bowel (SB). The appendiceal gut signature varies along its length. IA, Iliac artery; IV, iliac vein.

Peritoneal, Mesenteric, and Omental Abnormalities

ACUTE APPENDICITIS

Acute appendicitis is one of the most common causes of acute abdominal pain and is the most common indication for urgent abdominal surgery. It is more prevalent in older children and young adults.

Appendicitis is the result of luminal obstruction, usually by a fecalith or appendicolith. Less common causes include lymphoid hyperplasia, parasites, and primary and secondary tumors. The obstructed appendix is susceptible to mucosal ischemia and necrosis, which may progress to transmural inflammation, full-thickness infarction, and perforation (in ≈20% of cases).

The intention to preempt complications underpins the practice of early surgical intervention based on clinical assessment and laboratory tests. The “typical” clinical presentation is of vague central or epigastric abdominal pain with anorexia, progressing to nausea and vomiting, followed by migration of the pain to the right lower quadrant, and accompanied by fever, leukocytosis, and rebound tenderness. Any of these features may only be present to a variable degree or absent, so symptoms, signs, and laboratory tests are only moderately accurate for predicting appendicitis.

This strategy persists widely, although between one in three to five removed appendices will be healthy,^{7,8} in spite of over 20 years of evidence of the reduction in the number of unnecessary appendectomies using diagnostic imaging.^{9,10}

Sonography of the Normal Appendix

The normal appendix is elusive. It varies greatly in size (average, 8 cm; range, 1-24 cm) and position (pelvic and retrocecal

being the most common).¹¹ With TAUS, the appendix is identified as a thin, blind-ending tube, with a normal gut signature, in continuity with the cecal pole and arising several centimeters from the ileocecal valve.

Sonographic identification of the normal appendix is difficult and often only partial (see Fig. 4-8), because overlying loops must be compressed or displaced, and the healthy appendix is often coiled up. Identification rates for the normal appendix, in a population not presenting with suspected appendicitis, varies widely and is related to numerous factors, including technique, operator experience, examination time, and patient body habitus.

Sonography of Acute Appendicitis

The earliest sonographic descriptions of acute appendicitis identified the dominant diagnostic criteria as a noncompressible, blind-ending tube, with a maximum outside diameter (MOD) less than 6 mm. More recent studies have shown normal appendices with diameters of more than 6 mm and lumen distention by feces and/or air, confirming that this threshold diameter is unreliable unless included with other sonographic signs of appendiceal or extra-appendiceal inflammation^{12,13} (Box 4-1). Requiring a combination of these criteria to be present, together with significant clinical evidence of acute appendicitis, reduces the number of false-positive diagnoses (Fig. 4-9).

BOX 4-1 SONOGRAPHIC CRITERIA FOR APPENDICITIS

- Noncompressible blind-ending tube
- Lumen distention (MOD > 6 mm)
- Wall thickness > 3 mm
- Loss of gut signature
- Hyperemia on Doppler scanning
- Hyperechoic periappendiceal fat thickening
- Local transducer tenderness

Figure 4-9 Acute suppurative appendicitis. This 34-year-old woman presented with 3 days of RLQ (right lower quadrant) pain, with tenderness and guarding. **A.** Long view of thickened cecal pole (C) and appendix base (A) between the rectus (R) and psoas (P), with adjacent ileum (I). **B** and **C.** Axial power Doppler images of a hyperemic appendix on psoas (P) showing varying alterations in gut signature, local fat edema (F), and exudate on the serosal surface (arrow).

Appendicoliths are frequently identified in asymptomatic patients with otherwise normal US appearances and are not a reliable indicator of inflammation. In focal appendicitis, the MOD may not exceed 6 mm, and the diagnosis may be missed if the entire appendix is not visualized.^{14,15} The perforated appendix is even more elusive but may be most reliably identified by loss of the hyperechoic appendiceal wall layer (indicating transmural inflammation) and loculated periappendiceal or pelvic fluid collections.¹⁶ The negative predictive value of a scan in which the appendix is not identified differs widely across studies but is more reliable when the operator regularly identifies a normal or abnormal appendix.¹⁷

The strategic place for TAUS in the imaging of acute appendicitis is considered later.

Mimics of Acute Appendicitis

The imaging objectives for patients referred with suspected acute appendicitis are to identify the inflamed appendix or a normal appendix and any other cause of presentation. The most common differentials are acute diverticulitis, gynecologic causes, and mesenteric adenitis (in children), but prospective studies have identified a number of frequent and less frequent mimics (Box 4-2) and documented the relevant TAUS features.^{17,18}

These include a variety of conditions in which surgery is not indicated, and preoperative imaging diagnosis highly advantageous. In conditions such as epiploic appendagitis and rectus sheath hematoma, the sonographer has the diagnostic advantage of being guided to the point of tenderness.

DIVERTICULITIS

Acute colonic diverticulitis is a common cause for acute hospital admission.¹⁹ Patients are generally older adults but approximately 15% are younger than 40 years. The strongest clinical diagnostic indicators are left iliac fossa pain, absence of

Figure 4-10 Colonic diverticula. Axial image of the left colon reveals a thickened muscle layer (mp) interrupted by an echogenic diverticular neck (short arrow). The wall of the diverticulum is thin, with no muscle layer (long arrow).

BOX 4-2 MIMICS OF APPENDICITIS

Mesenteric adenitis
 Infectious enterocolitis
 Epiploic appendagitis
 Omental infarction

vomiting, and C-reactive protein (CRP) > 50, but all three are only present in 25% of presenters.²⁰ Computed tomography (CT) is routine in most cases for diagnostic certainty and to identify the complications of abscess, obstruction, fistula, and perforation. However, TAUS is highly sensitive and specific for uncomplicated acute diverticulitis and for the primary complication of pericolic abscess.²¹

Sonographic Features of Diverticula

Diverticula appear as bright “ears” outside the bowel wall, with acoustic shadowing caused by the presence of gas or inspissated feces. At higher probe frequencies, a thinned diverticular wall may be demonstrated with a reduced gut signature because of the absence of muscularis propria. The neck of a diverticulum may be identified as an echogenic band traversing hypoechoic circular muscle, which is often thickened (Fig. 4-10).

Sonographic Features of Diverticulitis

An isolated inflamed diverticulum²² is identified as an enlarged, echo-poor protrusion from the colon wall, with an ill-defined margin surrounded by echogenic noncompressible fat (Fig. 4-11). The gut signature is obliterated by the inflammation. Inspissated feces may be seen as a central shadowing echogenicity.

Figure 4-11 Acute diverticulitis. Axial image of the left colon showing asymmetric thickening of the echo-poor muscle layer around the echogenic lumen. A bright gas echo is demonstrated in the inflamed diverticulum (arrow).

Inflammation will commonly extend along the bowel, producing asymmetric or circumferential hypoechoic mural thickening that may be hyperemic on Doppler scanning. An intramural or pericolic abscess may be identified as an anechoic collection that may contain pockets of air or debris.

INFLAMMATORY BOWEL DISEASE

The prevalence of inflammatory bowel disease (IBD) in the United Kingdom is about 400/100,000, with ulcerative colitis (UC) almost twice as prevalent as Crohn's disease (CD). Most of these patients will require hospital assessment, and many will require acute admission: The lifetime risk for surgery is 20% to 30% for patients with UC and up to 70% to 80% for CD, depending on disease severity and location.²³

The diagnosis of IBD is made by clinical assessment, supported by a combination of laboratory tests, endoscopy and imaging. Establishing the location and extent of inflammatory lesions is critical to diagnosis, prognosis, and therapy. In CD, the behavior of disease at each site of involvement determines the likely clinical course. Penetrating disease producing fistulas and abscesses and stricturing disease results in episodes of obstruction. Although the location of disease is relatively stable over time, the course often changes.²⁴

Sonographic Evaluation

US is an accurate technique for the diagnosis of suspected IBD and evaluation of disease activity.^{25–27} It is less accurate for disease proximal to the ileum (L4) and for the rectum. However, over 70% CD patients have ileal or ileocolic disease at diagnosis.²⁴

As with all imaging modalities, the features of IBD overlap with those of a wide range of intestinal pathologic conditions. A specific diagnosis of UC or CD can seldom be made with confidence on imaging alone, but specific features such as skip lesions, longitudinal ulcers, and fat wrapping should be sought.

Bowel Wall Thickening. The primary imaging feature of IBD is bowel wall thickening (BWT). US has been shown to identify

Figure 4-12 Cobblestone mucosa in Crohn's disease. This is a long image of the ileum, with the lumen filled with edematous mucosal islands (M). The outer layers of the gut signature are preserved (arrows).

Figure 4-13 Acute ileitis in Crohn's disease. Shown are long (A) and axial (B) images of an ileal loop over the psoas (P) and iliac artery (IA). Gas-filled ulcers penetrate the thickened mucosa and submucosa (arrows). LN, Adjacent lymphadenopathy.

wall thickening in patients with suspected CD with a sensitivity of 88% and specificity of 93% at a BWT threshold of 3 mm or more and a sensitivity of 75% and specificity of 97% at a BWT threshold of more than 4 mm. In UC, BWT can be used to identify the extent and grade the severity of inflammation and the response to therapy.²⁸

Alteration in Gut Signature. The ability of TAUS to resolve the layers in a healthy bowel wall gives the potential to identify and characterize inflammatory behavior in wall layers, even at sub-threshold BWT. TAUS of inflamed segments may show the gut signature to be preserved, indistinct, or lost.²⁹

Isolated thickening of the mucosa may be accompanied by interruption of the lumen interface echo (layer 1) because of sloughing of the mucosal surface and/or tiny bright echoes caused by gas in the mucosal ulcers. In severe cases, the mucosa may be thinned by sloughing of necrotic tissue. The combination of ulcers and edematous mucosal islands produces the classic cobblestone appearance (Figs. 4-12 and 4-13).

In UC and CD, inflammation may be confined to the mucosa or mucosa and submucosa, resulting in thickening of these layers alone. Minimal thickening of the superficial layers may be judged in comparison with the muscularis propria, which is normally the thickest layer in all states of contraction.

In UC, severe inflammation extending into the submucosa reduces the echogenicity to the level of the adjacent muscle, producing a full-thickness hypoechoic ring. Hypoechoic wall thickening with complete loss of signature in CD indicates transmural inflammation, which may extend to produce an

Figure 4-14 Acute ileitis in Crohn's disease. Power Doppler signals indicate hyperemia of acute, active, inflammatory CD ileitis.

irregular, mixed, hypoechoic inflammatory exudate on the serosal bowel surface. These changes may be circumferential or focal. Inflamed and normal bowel may be identified on the same axial circumference (skip lesion) that is strongly indicative of CD. Wedges of low-echo transmural inflammation on the mesenteric border have been shown to correlate with longitudinal ulcers (Fig. 4-14).³⁰ These are features of penetrating disease, with a high risk of abscess and fistulation.

Vascular Changes and Disease Activity. Actively inflamed bowel segments have an increased blood flow, which may be demonstrated with color Doppler or power Doppler imaging (see Fig. 4-14). Studies have shown this phenomenon to be helpful for distinguishing active inflammatory lesions from fibrotic strictures and monitoring response to medical therapies.³¹ Evidence indicates that the use of US contrast media may further increase the diagnostic confidence when assessing perfusion and help quantify this phenomenon.³²⁻³⁵

Fat Wrapping. Cytokines released in response to transmural inflammation stimulate proliferation of mesenteric or subserosal fat, which creeps or wraps around the inflamed bowel segment. This sign is determined to be present when more than 50% of the involved bowel circumference is encased and is a specific feature of transmural CD (Fig. 4-15). Fat wrapping correlates with histologic evidence of transmural inflammation and associated complications, such as fistulation. However, fat

wrapping is not a reliable indicator of the length of an involved CD segment because it does not occur over areas of more superficial disease.³⁶

Locoregional Lymphadenopathy. Active intestinal CD is usually accompanied by mild to moderate lymphadenopathy in the adjacent mesentery.

Stricturing Crohn's Disease. Narrowing of the bowel lumen sufficient to cause impaired intestinal function and obstructive symptoms may be seen in active inflammatory segments (hot strictures) and in segments in which fibrosis predominates (cold strictures). Spasm and edema contribute to the narrowing of active disease segments and may rapidly respond to medical therapy. Persistent symptomatic stricture is the most common indication for surgery.

In experienced hands, TAUS accurately detects bowel stenosis, particularly of more severely narrowed lesions likely to require surgical intervention, in which prestenotic dilation may make a short lesion conspicuous.³² Active inflammatory strictures are hyperemic compared with normal bowel and with fibrotic strictures. Color and power Doppler demonstrate no vascular activity in healthy bowel wall but both demonstrate increased flow in the inflamed bowel wall and inflammatory masses.

Penetrating Crohn's Disease. About one in six patients with CD have penetrating lesions (abscess, fistula, inflammatory mass) at the time of diagnosis.

Abscess and Phlegmon. Transmural inflammation extending out to and beyond the serosal surface may be seen with US as an irregular, mixed, low-echo inflammatory exudate on the serosal surface, a mixed low-echo inflammatory mass between bowel loops (phlegmon), or an irregularly thick and walled collection with a liquid center (abscess). Abscesses may form between bowel loops or in adjacent structures, such as the abdominal wall (see Fig. 4-15).

Fistula. Penetrating disease may progress beyond the serosal surface and interloop space to adjacent structures, creating an abnormal communication between the lumen of the disease bowel segment and adjacent bowel loops or any adjacent hollow organ (e.g., uterus, bladder).

With US, fistulas are identified as irregular tubular hypoechoic tracks, within which small hyperreflective air bubbles may occasionally be demonstrated. However, the presence of adjacent, indrawn, angulated bowel loops connected by mixed hypoechoic inflammatory exudate is highly suspicious of fistulation (Fig. 4-16).³⁷

Figure 4-15 Penetrating Crohn's disease. Shown is an axial image of an inflamed ileum (I), with fat wrapping (curved arrows) and full-thickness penetration (broken arrow) extending to an adjacent abscess (A).

Figure 4-16 Crohn's disease fistula.

A. Ultrasound image of CD enterocolic fistula. Angulated ileal (short arrow) and colon (long arrow) loops are connected by echo-poor fistula (very small arrows) with moving, bright gas echoes in real time. **B.** CT scan of CD enterocolic fistula. This same-day CT scan confirms an inflammatory mass involving the small and large bowels extending onto the posterior pelvic brim. A tiny gas bubble marks the fistula (arrow). (From Rodgers PM, Verma R: Transabdominal ultrasound for bowel evaluation. *Radiol Clin North Am* 51:133-148, 2013.)

MIMICS OF INFLAMMATORY BOWEL DISEASE

Many of the imaging features of IBD are nonspecific and are shared with a wide range of pathologic conditions. The differential diagnoses relevant to the clinical presentation must be considered and imaging features sought to aid differentiation.

BOWEL ISCHEMIA

Bowel wall ischemia may result from impaired blood supply (embolic, stenotic, or diminished cardiac output) or drainage (mesenteric venous thrombosis). Depending on the cause, the injury may be focal or diffuse, range from superficial mucosal to full thickness, and vary in severity from mild to fulminant and life-threatening. The colon is more vulnerable to ischemic injury; the left colon is the most commonly affected segment.

The clinical picture is typically an older patient with abdominal pain, diarrhea, and rectal bleeding, with few clinical signs for the severity of symptoms. Ischemia produces mucosal and intramural necrosis, with associated edema and hemorrhage.

The chief sonographic features of bowel ischemia are marked circumferential thickening of a longer (>10 cm) bowel segment with reduced perfusion (little or no Doppler flow). The gut signature may be preserved in superficial injury, and the submucosal layer may be thickened by edema and hemorrhage. Full-thickness injury is more commonly accompanied by loss of the gut signature and peri-intestinal altered fat or fluid.^{38,39} Intramural air may be identified by highly echogenic reflectors with acoustic shadowing. US contrast agents can demonstrate persisting perfusion and predict likely recovery in those with less severe injury (Fig. 4-17).⁴⁰ Atypical presentations in younger patients with small bowel or more proximal gastrointestinal (GI) injury may be the result of autoimmune vasculitides, drugs (e.g., oral contraceptives, cocaine), fibromuscular dysplasia, and other rare conditions. These may mimic Crohn's lesions, so documenting the Doppler findings is critical.

INFECTIOUS ENTEROCOLITIDES

Pseudomembranous Colitis (PMC)

Pseudomembranous colitis (PMC) is a common, toxin-induced manifestation of intestinal infection *Clostridium difficile*. *C. difficile* is the cause in 15% to 25% of cases of antibiotic-associated diarrhea.⁴¹

Sonographically, PMC is characterized by diffuse large bowel, often so severe that it effaces the lumen. The mucosa and submucosa become indistinguishable, with a mixed heterogeneous striated echo pattern. The lumen and mucosal layer are interrupted by ulcers; and the coalescent slough of pseudomembranes is identified as linear echogenic structures in the lumen (Fig. 4-18). Ascites is a common feature.^{42,43}

Infectious Ileocolitis

Yersinia, *Campylobacter*, and *Salmonella* bacteria are well-known causes of acute, usually self-limiting, diarrheal illnesses but less commonly may produce an enteric infection confined to the ileocecal region. In such cases, patients present with right iliac fossa pain and tenderness, and diarrhea may be minimal or absent. In more acute cases, this may result in unnecessary appendectomy or more protracted cases may be mistaken for Crohn's disease or an appendix mass.

Figure 4-17 Ischemic bowel. **A.** Longitudinal section of the descending colon (arrows) shows hypoechoic wall thickening, with barely visible stratification. Color Doppler sonography (not shown) detected only minimal flow in the periphery of the bowel wall. **B.** Contrast-enhanced ultrasound clearly demonstrated vascularization of this segment (arrows), requiring no urgent surgical intervention. (From Hollerweger A: Colonic diseases: The value of US examination. *Eur J Radiol* 64:239–249, 2007.)

Ultrasound reveals a symmetric thickening of the wall of the terminal ileum and cecum confined to the mucosal and submucosal layers, with no extension to the muscularis or serosa, or beyond into the mesentery. It has been reported that the extent of cecal and colonic involvement may vary with the specific

Figure 4-18 Pseudomembranous colitis. TVUS shows marked colon wall thickening, with mucosal breaks, blurred gut signature, and strong reflectors (pseudomembranes) formed by coalescing slough (arrows).

pathogen.⁴⁴ Local mesenteric lymph nodes are usually enlarged. The appendix is normal.

Intestinal Tuberculosis

Nonspecific symptoms such as abdominal pain, weight loss, anemia, and fever predominate, but patients may present with symptoms of intestinal obstruction or a palpable abdominal mass.⁴⁵ Tuberculosis usually involves the ileocecal segment but isolated ileal or jejunal disease does occur and is a particular feature of atypical varieties.

Ultrasound features include bowel thickening with luminal narrowing and superficial or deep ulcers, typically involving the terminal ileum, ileocecal valve, and cecum (Fig. 4-19). Lymphadenopathy is common and may form conglomerate masses. Bowel loops may be matted together by interloop exudates or abscesses. Ascites or peritoneal thickening may be identified.⁴⁶

Strategic Place for Ultrasound in Bowel Imaging

The current evidence-based consensus guidelines on imaging in IBD, produced jointly by ECCO (European Crohn's and Colitis Organization) and ESGAR (European Society of Gastrointestinal and Abdominal Radiology), document the significant contribution made by TAUS to the multimodality approach to IBD diagnosis and management.²⁷ Most of this is elective, and the high level of operator skills needed for bowel sonography can be matched to the specific clinical need. Emergent

Figure 4-19 Ileocecal tuberculosis. There is an irregular, echo-poor contracted cecum (short arrow), ileocecal valve (arrowhead) and thickened terminal ileum, with preserved stratification (long arrow).

presentations are more likely to need management by CT, with the attendant concerns of radiation dose accruing over a lifetime of disease.

The role of TAUS in acute clinical presentations is more problematic, not least because of issues of training and availability outside of office hours. Prospective comparative studies of the performance of CT and US in acute appendicitis favor CT (diagnostic value of graded compression ultrasonography—summary sensitivity of 0.78, summary specificity of 0.83; diagnostic value of CT—summary sensitivity of 0.91, summary specificity of 0.90).⁴⁷ The authors of this meta-analysis and many others have only designated TAUS as a first-line test for children and younger or pregnant women to avoid exposure to ionizing radiation.^{48,49} However, equivocal CT findings are a significant problem, with up to one third of these individuals having acute appendicitis.⁵⁰ TAUS can be a useful adjunct to CT in equivocal cases.^{51,52}

A stratified approach commencing with ultrasound using a high-frequency probe and proceeding to CT for inconclusive cases has been recommended.⁵³⁻⁵⁵ Low-dose CT techniques and/or limited scan areas have been demonstrated as effective while reducing radiation.⁵⁶ The effectiveness of the locally adopted imaging protocols should be reflected in the local negative appendectomy rate, perforation rate, and radiation dose monitoring.

Bowel Wall: Pathologic Changes

How to Examine the Bowel with MDCT
Evaluation of the Abnormal Gut

Mesenteric and Omental Fat Disease

Blood Vessels
Serosal and Subperitoneal Fat Density
Lymph Nodes
Calcifications

Multidetector computed tomography (MDCT) is currently the premier imaging technique for evaluating luminal, mural, and mesenteric abnormalities of the gastrointestinal tract. Although magnetic resonance (MR) enterography is rapidly gaining acceptance as the method of choice in evaluating patients with Crohn's disease, MDCT examinations of the entire abdomen and pelvis can be acquired in seconds with near-isotropic voxels, allowing for high-quality and clinically useful volume imaging. The CT datasets can be viewed in any plane, and 3D techniques can be used to display large datasets effectively and graphically in a user-friendly format that is understandable to referring physicians.¹⁻³

Lumen Opacification

Proper distention and marking of the bowel lumen are vital in detecting mural thickening and excluding mural masses and mesenteric and omental disease. There are a number of methods available to accomplish this goal; the choice depends on the clinical setting.

In the emergent setting, in which bowel obstruction or intestinal ischemia is suspected, the intestinal secretions are usually sufficient to highlight the lumen, especially in a high-grade

bowel obstruction. Orally administered contrast may be vomited and may remain in the stomach because of absent or diminished gastrointestinal motility. Finally, in cases of suspected ischemia, positive oral contrast media often hamper the creation of CT angiograms.

As part of a general survey examination of patients with no localizing signs or symptoms, a study performed with positive luminal contrast material is often obtained. As a caveat, the assessment of mural and mucosal enhancement of the gut may be compromised with the positive contrast material. Additionally, positive intraluminal contrast will interfere with CT angiography and some 3D techniques.

Air or carbon dioxide as an intraluminal contrast agent is used in the setting of CT gastroscopy and colonography.

POSITIVE CONTRAST AGENTS

Positive contrast opacification (>75-100 HU) of the gut is accomplished by giving 1% to 2% barium suspensions or 2% to 3% solutions of iodinated water-soluble agents (Fig. 5-1). The low percentage of barium requires commercial preparations made specifically for CT, in which additives are used to ensure that the barium remains in suspension.

In most patients, contrast material will reach the distal ileum within 45 minutes after initiation of drinking. Prolonged transit times are to be anticipated. Some common conditions altering the transit time include recent postoperative status, serum electrolyte disturbances, collagen vascular diseases (e.g., scleroderma), hypothyroidism, and intestinal obstruction. Conversely, patients who are hyperthyroid, have syndromes with associated increased intestinal motility (e.g., carcinoid, islet cell tumor), or have infections (e.g., cryptosporidiosis, giardiasis) will display a significantly accelerated intestinal transit time.

The choice between oral barium suspensions and water-soluble agents is dictated by the experience and preference of the radiologist. Water-soluble agents should be used exclusively for patients with abdominal trauma or a suspected perforated viscus, those who have a high likelihood of immediate surgery, and as an aid in percutaneous CT biopsy or other interventional procedures.

NEUTRAL CONTRAST AGENTS

Neutral contrast agents (0-25 HU) have several advantages over positive contrast agents for evaluating mucosal, mural, and serosal disease (Fig. 5-2).⁴⁻¹¹ They allow excellent depiction of mural enhancement of the gut without the algorithm under-shoot or overshoot that may accompany intraluminal high-attenuation, positive contrast, and low-attenuation gas. Neutral

Figure 5-1 Positive contrast opacification. Positive contrast within the lumen of the gut provides lumen distention and helps differentiate a collapsed bowel from masses, adenopathy, and abscesses. In this obese individual, the mesenteric vessels are well depicted.

Figure 5-2 Neutral contrast opacification. Neutral contrast not only distends the lumen but also provides for easier evaluation of mural enhancement and the mesenteric vessels.

contrast agents also facilitate the performance of CT angiography and other three-dimensional techniques. Neutral contrast agents include water, milk, lactulose, 0.1% solution of barium (VoLumen; Bracco Diagnostic, Princeton, NJ), and water with mannitol or polyethylene glycol. Water can be administered as an effective neutral contrast agent for the upper gastrointestinal tract, especially the stomach and duodenum. However, it is less effective in distending the more distal bowel because it is normally absorbed before reaching the distal ileum.

These neutral agents are also helpful when performing CT angiography for staging and preoperative evaluation of hepatic, biliary, and pancreatic malignancies. Regardless of the agent, consistent opacification and/or distention of the jejunum remains a challenge. Unlike the standard small bowel series, periodic overhead films are not obtained before a CT. Thus it is impossible to determine the best time to scan in relation to proximal small bowel opacification and distention.

GAS CONTRAST

Gaseous distention of the stomach is important when evaluating mucosal and mural disease. It has been used with great success in CT gastrography for the diagnosis and staging of upper gastrointestinal malignancies.¹²⁻¹⁴

For CT colonography, room air or carbon dioxide is insufflated per rectum (Fig. 5-3). Adequate gaseous distention of the colon is very important for image interpretation because significant lesions may be obscured in a collapsed segment of colon.¹⁵⁻¹⁹ A complete discussion of this technique is presented in Chapter 53.

Vascular Opacification

Opacification of the blood vessels is essential for complete evaluation of inflammatory, infectious, neoplastic, vascular, and traumatic diseases of the gastrointestinal tract. Obviously, this cannot be performed in all clinical settings (e.g., in cases of poor renal function or poor venous access). For general diagnostic cases, 100 to 150 mL (depending on concentration) of nonionic contrast is administered at a rate of 3 mL/s with a power injector. If CT angiography or other 3D techniques are to be performed, the rate is increased to 5 mL/s. Many sites use some form of bolus tracking as a method of timing the scan in relation to the level of arterial opacification.

One of the advantages of MDCT is that multiple datasets can be acquired with a single bolus of contrast. The following possible imaging times may be used when imaging the abdomen and pelvis—unenhanced, early arterial phase (20 seconds); late arterial-enteric phase (40 seconds); portal venous phase (70-90 seconds); equilibrium phase (210 seconds); and delayed phase (15-20 minutes).

For general survey abdominal imaging, obtaining scans during the portal venous phase is adequate. When assessing the viability of bowel, searching for a source of gastrointestinal hemorrhage, evaluating the cirrhotic liver, and searching for hypervascular metastases, it is useful to obtain noncontrast scans as well as scans during the later hepatic arterial and portal venous phases. When CT angiography is performed, scans should be obtained during the early arterial phase. The enteric phase corresponds to the late arterial phase and has been found useful for evaluating Crohn's disease activity.

Figure 5-3 Gas opacification. Distention of the lumen of the gut is an important part of CT colonography.

Normal Bowel Wall

Almost all significant pathology of the bowel wall results in mural thickening, which is often accompanied by changes in the attenuation of the bowel wall caused by edema, hemorrhage, tumor, fat, or gas. Two of the most common pitfalls in interpreting CT examinations of the gut are (1) confusing an insufficiently distended loop of bowel for pathologic thickening and (2) mistaking an inadequately opacified bowel loop for an abdominal mass. Techniques for achieving lumen distention are in the preceding section.

ESOPHAGUS

The esophagus has a length of 23 to 25 cm in the average adult. The wall of the distended esophagus is 3 mm in thickness (Fig. 5-4). When the esophagus is not distended, the wall may approach 5 to 7 mm. It may be very difficult to differentiate diffuse and even focal esophageal disease if the lumen is not distended (a common occurrence). Furthermore, a hiatal hernia commonly has the appearance of focal wall thickening. The cervical esophagus lies posterior to the trachea in the midline. It may normally bulge into the posterior aspect of the trachea because of the limited space of the neck.

Figure 5-4 Normal esophagus. On this sagittal reformatted image of the thorax, the normal esophagus is depicted as a thin-walled tubular structure. Note that it courses posterior to the left mainstem bronchus (red arrow) and left atrial appendage (black arrow).

At the level of the thoracic inlet, the esophagus courses to the left of the midline and then lies adjacent to the left main stem bronchus and pericardium of the left atrium in the mid-thorax. More distally, the esophagus lies anterior to the descending aorta to the left of the midline as it enters the esophageal hiatus of the diaphragm. Normally, the thoracic esophagus should not indent the trachea, and there should be a triangle of fat between the aorta, spine, and esophagus distally. In patients with invasive esophageal carcinoma, the trachea is bowed along its posterior aspect by the esophageal tumor. More distally, invasive esophageal neoplasms obliterate the triangle of fat.

Contrast-enhanced examinations should show uniform mural enhancement of the esophagus, without mural stratification.

STOMACH

The stomach is a functionally and anatomically dynamic organ, and its appearance depends on the degree of luminal distention and gastric location (Fig. 5-5). For the well-distended, nondependent gastric fundus and body, a wall thickness of up to 5 mm is considered normal.²⁰ The mural thickness of the antrum, however, is affected by anatomic and functional factors that make it normally thicker than other portions of the stomach. The gastric smooth muscle, particularly the circular layer, is thicker and denser in the antrum compared with more proximal portions of the stomach. Periodic concentric and eccentric antral contractions, as seen fluoroscopically, also contribute to the apparent mural thickening of the stomach.

When the normal stomach is distended with neutral contrast, enhancement of the mucosa may be seen, highlighted against the lower attenuation mucosa and muscularis propria. Up to 25% of patients show linear submucosal low attenuation

Figure 5-5 Normal stomach. Axial (A) and coronal reformatted (B) images show a thin gastric wall. Often, the antrum is slightly thicker than the more proximal stomach.

or mural stratification in the antrum on contrast-enhanced MDCT examination. This may be partly the result of fat deposition in the submucosa.

SMALL BOWEL

The normal small bowel is approximately 22 feet long and is suspended by a root that measures 6 to 9 inches and courses from the level of the ligament of Treitz caudally to the level of the ileocecal valve. As with conventional barium small bowel examinations, there are more valvulae conniventes in the jejunum than in the ileum. The normal small bowel wall measures between 1 and 2 mm when the lumen is well distended with a positive, neutral, or air contrast medium (Fig. 5-6). When collapsed, the normal mural thickness of the small bowel measures between 2 and 3 mm.

The normal small bowel wall appears to have the greatest level of enhancement during the enteric phase (approximately 40 seconds, after initiation of the contrast injection).²¹ This investigation did not take into account the location of the small bowel when assessing bowel wall enhancement. Some investigators think that this is the ideal time to scan in patients with Crohn's disease. Other investigators, using timed MR scanning after the injection of contrast, have shown that the maximal difference between normal and active inflammatory

Figure 5-6 Normal small bowel and colon. Coronal reformatted image shows nice distention of the small bowel and colon by positive contrast. The high-density intraluminal material limits assessment of the enhancement of the bowel wall.

small bowel Crohn's disease occurs much later, even several minutes after contrast injection.²² Furthermore, one investigation has shown that there is no significant difference in detecting the CT features of Crohn's disease at 40 and 70 seconds postcontrast.²³

Regardless, the wall of collapsed segments of the small bowel has a greater attenuation than the wall of distended loops. Also, because the duodenum has more folds than the jejunum and the jejunum has more than the ileum, the duodenum enhances more than the jejunum and the jejunum enhances more than the ileum.²⁴ Because collapsed small bowel loops have increased attenuation, similar to that of inflamed bowel loops, secondary findings of infectious or inflammatory small bowel disease (e.g., stratified enhancement pattern, engorged vasa recta, creeping fat of the mesentery, enlarged lymph nodes) should be considered (see Chapter 41).

COLON

The thickness of the colon wall as imaged on MDCT depends on the degree of distention. Fecal contents, fluid, colonic redundancy, and muscular hypertrophy (myochosis) make accurate determination of the true colonic wall thickness difficult. The normal colon wall (see Fig. 5-6) is normally less than 4 mm thick with proper distention. The normal wall is typically homogeneous in attenuation. With obesity becoming increasingly prevalent, submucosal fat is being identified in otherwise normal patients throughout the gut, but particularly in the colon.

Bowel Wall: Pathologic Changes

HOW TO EXAMINE THE BOWEL WITH MDCT

MDCT findings using thin section reconstructions (<1–2 mm), often overlapping, can be reconstructed in multiple planes. As in plain film radiography, orthogonal views are essential to assess the small bowel. We find that the axial and coronal planes are most helpful, with occasional sagittal reconstruction, especially if mesenteric artery occlusion is an important part of the investigation (i.e., ischemic bowel). Without orthogonal views, segments of the bowel may not be adequately assessed. Furthermore, in patients with Crohn's disease, strictures and fistulas may not be identified. As an added benefit, surgeons and gastroenterologists are more familiar with viewing the small bowel in the coronal plane.

When viewing MDCT depictions of the bowel, especially the small bowel, we find that the routine scrolling on a workstation from superior to inferior and back, as well as anterior to posterior, allows the radiologist to follow bowel loops from the jejunum to ileum in a continuous fashion. Also, viewing the images in this volume fashion, changing windows and levels as needed, can detect mural abnormalities and distinguish the small bowel from mesenteric processes. Viewing the bowel with narrow windows, similar to liver windowing and leveling, can facilitate detection of hypervascular small bowel tumors, vascular abnormalities of the bowel wall (arteriovenous malformations and Dieulafoy lesions), and the mural hyperenhancement identified in active, inflammatory Crohn's disease. Changing the window and level back to a soft tissue window after assessing the small bowel will facilitate identification of mesenteric abnormalities, which might have been missed using the narrow windowing and leveling. This dynamic volume interpretation is a demanding process but, once mastered on a modern interpreting workstation, can be performed rapidly and efficiently.

EVALUATION OF THE ABNORMAL GUT

Mural thickening is the pathologic hallmark of gastrointestinal disease. When evaluating the abnormal gut, the following features should be carefully analyzed: mural attenuation and enhancement patterns (Table 5-1); degree of mural thickening (Table 5-2); symmetry of bowel wall thickening (Table 5-3); and length of the diseased segment (Table 5-4). Wittenberg and colleagues described a classification system for the abnormal bowel wall as depicted by MDCT (Fig. 5-7).²⁵ Regardless of enhancement patterns, symmetry of the bowel wall thickening, and length of the diseased segment, the thicker the bowel wall, the more likely that neoplastic disease is present. As a good rule of thumb, confirmed in the literature as well as anecdotally, wall thickening of 1.5 cm or less is infectious and/or inflammatory and wall thickening more than 1.5 cm is neoplastic. Between 1 and 2 cm, there is overlap between the categories. Additionally, neoplastic disease tends to cause asymmetric wall thickening, but this general rule holds true for over 90% of cases.²⁶

White Attenuation Pattern

When the diseased segment of gut demonstrates contrast enhancement to a degree equal to or greater than that of venous opacification on the same scan, this indicates abnormal enhancement (Fig. 5-8A). Avid mural contrast enhancement is probably

TABLE
5-1

Patterns of Attenuation

- I. Homogeneous
 - A. Common
 1. Submucosal hemorrhage
 2. Lymphoma
 3. Small adenocarcinoma
 - B. Uncommon
 1. Infarcted bowel
 2. Pitfalls related to residual fluid
 3. Chronic Crohn's disease
 4. Chronic radiation injury
- II. Heterogeneous
 - A. Stratified attenuation
 1. Common
 - a. Ischemia
 - b. Infectious enterocolitis
 - c. Crohn's disease, ulcerative colitis
 - d. Vasculitis, lupus, Henoch-Schönlein purpura
 - e. Radiation
 - f. Bowel edema related to cirrhosis or low-protein state
 - g. Angioedema from angiotensin-converting enzyme (ACE) inhibitors
 2. Uncommon
 - a. Infiltrating scirrhous carcinoma (usually stomach or rectum)
 - b. Residual fluid and contrast material
 - c. Submucosal fat deposition
 - d. Pneumatosis
 - B. Mixed attenuation, common
 1. Large adenocarcinoma
 2. Gastrointestinal stromal tumor
 3. Mucinous adenocarcinoma

 - G. Lymphoma
 - H. Submucosal hemorrhage
- II. Asymmetric
 - A. Adenocarcinoma (mural or endoenteric)
 - B. Gastrointestinal stromal tumor (exoenteric)
 - C. Carcinoid tumor (mural or endoenteric)
 - D. Metastatic disease (mural or endoenteric)
 - E. Lymphoma (can be both symmetric and asymmetric)

Modified from Macari M, Balthazar EJ: CT of bowel wall: Significance and pitfalls of interpretation. *AJR* 176:1105–1116, 2001; Appendix 3, p 1116.

TABLE 5-4 Length of Mural Thickening

- I. Focal (<10 cm)
 - A. Common
 - 1. Diverticulitis, appendicitis
 - 2. Adenocarcinoma
 - B. Uncommon
 - 1. Lymphoma
 - 2. Tuberculosis
 - 3. Crohn's disease
- II. Segmental (10–30 cm)
 - A. Common
 - 1. Lymphoma
 - 2. Crohn's disease
 - 3. Infectious ileitis
 - 4. Radiation
 - 5. Submucosal hemorrhage (<15 cm, >1 cm thickness in relation to ischemia)
 - 6. Ischemia (>30 cm, <1 cm thickness in relation to hemorrhage)
 - B. Uncommon—systemic lupus erythematosus
- III. Diffuse
 - A. Common
 - 1. Ulcerative colitis
 - 2. Infectious enterocolitis
 - 3. Edema from low protein and cirrhosis
 - 4. Systemic lupus erythematosus
 - B. Uncommon—ischemia

Modified from Macari M, Balthazar EJ: CT of bowel wall: Significance and pitfalls of interpretation. *AJR* 176:1105–1116, 2001; Appendix 4, p 1116; and, Macari M, Chandarana H, Balthazar E, Babb J: Intestinal ischemia vs intramural hemorrhage: CT evaluation. *AJR* 180:177–184, 2003.

related to inflammation, vasodilation, and/or injury to intramural vessels with interstitial leakage of the contrast medium. This pattern of enhancement is usually seen in patients with acute inflammatory and infectious bowel disease, reflecting the hyperemic and hypervascular state found with acute inflammation and infection.

Vascular disorders such as shock bowel also may manifest with the white attenuation pattern. The increased vascular permeability and slowed perfusion that accompanies hypoperfusion permits the interstitial leakage of molecules of contrast material. Delayed venous drainage and altered vascular

Figure 5-7 Classification scheme for mural thickening of the gastrointestinal tract.

permeability are also responsible for this sign in patients with bowel ischemia.

On non-contrast-enhanced scans, intramural hemorrhage will produce a hyperdense bowel wall (Fig. 5-8B).

Gray Attenuation Pattern

In this pattern, thickened bowel wall shows little enhancement and a homogeneous attenuation comparable with that of enhanced muscle (Fig. 5-9). This pattern should only be diagnosed if the intravascular contrast levels are adequate. Malignancy should be suspected in thickened segments of gut that show minimal enhancement and do not exhibit mural stratification.

Adenocarcinomas of the gastrointestinal tract are endoenteric lesions and usually show the uniform, gray enhancement pattern unless there are focal regions of necrosis. Lymphomas are also endoenteric and usually show a greater degree of wall thickening, generally more symmetric than adenocarcinoma, and are also homogeneous in attenuation. Gastrointestinal stromal tumors and metastases are exoenteric (the epicenter of the mass is outside the bowel wall and lumen) and often cause mural thickening, but are typically inhomogeneous in attenuation. They also commonly ulcerate.

In patients with Crohn's disease, the presence of a thick nonenhancing segment suggests the fibrostenotic disease. However, fibrostenotic disease is almost always associated with some level of inflammation, in which case there will often be some level of stratified hyperenhancement (see Chapter 41).

Water Halo Pattern

The water halo pattern is usually seen in patients with active infectious, inflammatory, ischemic disorders of the gastrointestinal tract (Fig. 5-10). The bowel, when viewed in the axial plane, has a target or bull's-eye appearance. An enhancing, central, higher density mucosal layer is surrounded by a water density submucosa that in turn is surrounded by a higher density muscularis propria.

Fat Halo Pattern

Fat in the submucosa of the gut produces the fat halo pattern (Fig. 5-11). It has lower attenuation than the grayer tone of the water halo sign. Although this finding can be seen in the small bowel and colon because of chronic Crohn's disease and in the colon because of ulcerative colitis, submucosal fat deposition in

Figure 5-8 White enhancement pattern. **A.** Coronal reformatted image shows a uniformly, densely enhancing distal ileal loop caused by active Crohn's disease. There is disproportionate fat stranding surrounding this inflamed loop. Note the engorged vasa recta. This pattern is seen in patients with acute inflammatory bowel disease and shock bowel. **B.** On unenhanced scans, a hyperdense bowel wall (arrows) can be seen with intramural hemorrhage. A thickened segment of ileum is identified in this patient with systemic lupus erythematosus.

Figure 5-9 Gray enhancement pattern. The thickened wall of the gastric antrum in this patient with adenocarcinoma of the stomach shows uniform, gray enhancement. Malignancies do not typically demonstrate mural stratification.

the stomach, duodenum, small bowel, and colon is now understood to be a fairly common, benign finding, generally found in obese individuals.^{27,28} This finding may also be seen in patients who are not obviously obese (Fig. 5-12). The rapid accumulation of submucosal fat has also been reported in patients undergoing cytoreductive surgery for lymphoproliferative and myeloproliferative disorders and graft-versus-host disease.

Black Attenuation Pattern

Bowel pneumatosis should always be considered as a sign of acute injury—ischemic, infectious, or traumatic (Fig. 5-13). Any disease process that compromises the integrity of the mucosa can introduce intramural gas. The presence of intramural gas can herald an abdominal catastrophe and must be viewed with suspicion. It can be seen as a benign process in patients with pneumatosis cystoides intestinalis, scleroderma, or other connective tissue disease that weakens the integrity of the bowel wall and in the setting of enteral catheters (Fig. 5-14).

One must detect small intramural collections of gas and avoid confusing them with pseudopneumatosis. Gas bubbles can cling to the mucosa in the dependent portion of the bowel lumen, adjacent to the wall and not rising to the nondependent lumen, adjacent to the wall. Furthermore, in some patients with viscous intestinal secretions, gas may be displaced in the periphery of the lumen circumferentially. Differentiating this from pneumatosis at times can be very difficult. Careful scrutiny of the gas location in relation to the wall using wide, lunglike windows, is helpful in making this differentiation. Pneumatosis should be surrounded on all sides by the small bowel wall. Similar to the small bowel, gas bubbles in the colon may become trapped between fecal debris and mucosa.

Figure 5-10 Water halo enhancement pattern. **A.** Axial CT of the descending colon in a patient with cytomegalovirus colitis. **B.** Corresponding line diagram. Mural stratification with a target pattern is typical of acute infectious, inflammatory, and ischemic enterocolitides. There is an inner ring of enhancing mucosa surrounded by a hypodense ring caused by submucosal edema, which in turn is surrounded by enhancing muscularis propria.

Figure 5-11 Fat halo enhancement pattern. In this patient with chronic ulcerative colitis, fat is present within the submucosa. The lumen of the rectum is narrow, and there is an increase in the presacral space because of fatty deposition.

Figure 5-12 Fat halo enhancement pattern. This nonobese patient (body mass index [BMI] = 23.73) is not on steroids and does not have Crohn's disease. There is fat in the submucosa of the terminal ileum (arrow).

Figure 5-13 Black enhancement pattern. **A.** Scan of the pelvis displayed with lung windows shows intramural gas with ischemic necrosis of a segment of ileum. **B.** CT scan of the liver of this patient shows extensive portal venous gas.

Figure 5-14 Black enhancement pattern. Plain abdominal x-ray (A) and MDCT scan (B) show intramural gas (arrows) in multiple loops of small bowel, 1 day after the operative placement of a jejunal feeding tube.

Mesenteric and Omental Fat Disease

Careful evaluation of the attenuation, vascularity, and lymph nodes of the fat within the subperitoneal spaces surrounding the gut provides important information about the disease in the adjacent bowel segment. There are six abdominal mesenteries—small bowel mesentery, transverse mesocolon, sigmoid mesocolon, ascending mesocolon, descending mesocolon, and mesoappendix. There are two omenta, the lesser and greater omentum. They may be involved by any number

Figure 5-15 Engorged vasa recta. There is engorgement of the vasa rectae of the ileocolic mesentery in this patient with Crohn's disease, the so-called comb sign. Infectious and inflammatory enterocolitides tend to be more vascular than malignancies.

of ischemic, infectious, inflammatory, trauma, and malignant disorders.

BLOOD VESSELS

When a thickened segment of gut is supplied by engorged blood vessels (vasa recta along the mesenteric border), the disease most likely is infectious or inflammatory (Fig. 5-15). In the small bowel, mural thickening can be seen in Crohn's disease and lymphoma. If the vasa recta supplying the affected segment are engorged (often referred to as the comb sign), then the disease is most likely Crohn's disease. Similarly, in a patient with mural thickening of the sigmoid colon, the presence of engorged vasa recta (the caterpillar sign) is more suggestive of the diagnosis of diverticulitis as opposed to colon cancer.

SEROSAL AND SUBPERITONEAL FAT DENSITY

Comparing the degree of soft tissue stranding in the fat surrounding an abnormal segment of gut and the associated mural thickening is an important clue to diagnosing patients with acute abdomen. Inflammatory condition such as appendicitis, diverticulitis, epiploic appendagitis, and omental infarction are associated with disproportionate fat stranding (Fig. 5-16). In other words, the amount of fat stranding is greater than the degree of mural thickening.²⁹ In patients with small bowel obstruction, engorged vasa recta supplying the obstructed

Figure 5-16 Disproportionate fat stranding: Epiploic appendagitis. There is an inflamed ischemic epiploic appendage (arrow) adjacent to a slightly thickened segment of descending colon. Note the stranding in the adjacent fat.

segment is a finding that can be seen in closed loop obstruction and in patients with venous compromise.

Creeping fat of the mesentery is a common finding in patients with Crohn's disease. This abnormal fat often demonstrates prominent lymph nodes and engorged vasa recta (see Chapter 38) and causes separation of bowel loops. Small bowel carcinoid tumors induce an intense desmoplastic reaction in the mesenteric fat. In classic cases, there is an enhancing, central soft tissue mass in the mesentery. There are radiating spokes from the mass extending peripherally in the mesenteric root, extending outward toward the small bowel, thickening the small bowel wall, and creating a retractile appearance on CT (see Fig. 5-15).

Neoplasms also produce changes in the subperitoneal fat of the adjacent mesentery or omentum. Tumor invasion into the pericolic fat results in more sharply defined and thicker dense strands than those found with inflammation and infection. Spikelike densities correlate with pathologic findings of tumor extension through the serosa into perienteric fat.

LYMPH NODES

The evaluation of mesenteric and omental lymph nodes is an important part of assessing abnormal bowel disease (Fig. 5-17). Mesenteric lymph nodes are enlarged if they exceed 5 mm in

Figure 5-17 Adenopathy. Enlarged lymph nodes are identified in the mesorectal fat in this patient with a thickened rectal wall caused by adenocarcinoma. The presence of adenopathy favors a malignant as opposed to a benign cause of the bowel wall thickening.

the short axis,³⁰ but mesenteric lymph nodes can be caused by infection, inflammation, and tumor (Fig. 5-18). As a general rule, when the lymph node size is disproportionately greater than the mesenteric or omental inflammatory response, a malignancy should be considered. The number and location of these lymph nodes is also another important consideration.³¹

In patients with mural thickening of the sigmoid colon, differentiating colon carcinoma from diverticulitis is a common clinical problem. Patients with carcinoma often have large lymph nodes in the sigmoid mesocolon and a greater degree of mural thickening, and tend to have acute, irregular, and eccentric margins. Diverticulitis produces disproportionate fat stranding, the length of involvement is longer, and lymph nodes are typically normal in size.

Patients with Crohn's disease will often have enlarged mesenteric lymph nodes (sometimes as large as 1.5 to 2 cm in the short axis, but generally <1.5 cm in the short axis) in the mesentery adjacent to the involved segment of gut. When patients with Crohn's disease have nodes more than 1.5 to 2 cm in the short axis, the radiologist must scrutinize the adjacent bowel wall for the possibility of a complicating adenocarcinoma or lymphoma (if the patient has been on long-term, anti-tumor necrosis factor [TNF] therapy). Gastrointestinal infections and mesenteric adenitis often produce mildly enlarged lymph nodes as well. However, adenopathy in these cases is less impressive than that found in patients with lymphoma.

The attenuation of the lymph nodes can also help narrow the differential diagnosis. A fat-containing lymph node can be

Figure 5-18 Calcifications. Mesenteric calcifications are identified in the ileocolic mesentery in this patient with an obstructing ileal carcinoid (arrow). Note the increased stranding of the mesentery resulting from the desmoplasia induced by the vasoactive peptides secreted by these tumors.

seen in patients with sprue and giant cavity lymph node syndrome. If the low-attenuation lymph node demonstrates a rim of contrast enhancement or calcifications, infections such as tuberculosis, other mycobacterial infections, and histoplasmosis should be considered. Mucinous tumors of the colon may also produce low-attenuation metastatic lymph nodes. In patients with acquired immunodeficiency syndrome (AIDS), high-attenuation lymph nodes suggest the diagnosis of Kaposi's sarcoma.

Carcinomas of the stomach, small bowel, and colon may only infiltrate a lymph node without necessarily increasing its size. Accordingly, any normal-sized lymph nodes near a gastrointestinal tract malignancy, especially if three or more in number, must be viewed with suspicion. Local lymph nodes associated with carcinoid tumors may calcify.

CALCIFICATIONS

Omental and mesenteric calcifications can develop in a number of benign and malignant disorders of the abdomen and pelvis. Carcinoid tumor often presents with a calcified mass in the mesentery associated with tethering of adjacent small bowel loops (see Fig. 5-18). The vasoactive peptides secreted by these tumors cause a local desmoplastic reaction, with retraction of the mesentery, kinking of the adjacent loops, and mural

Figure 5-19 Calcifications. Axial (A) and coronal (B) MDCT scans show mesenteric calcifications within a soft tissue mesenteric mass caused by sclerosing mesenteritis. Although the calcification is more confluent and dense (arrow) than generally seen in carcinoid, only a biopsy can confirm the diagnosis.

thickening. Sclerosing mesenteritis is another entity commonly causing intense, often confluent, dense calcification in a mesenteric root mass (Fig. 5-19). It can be difficult to differentiate sclerosing mesenteritis from a carcinoid, but in general the calcification in sclerosing mesenteritis is much more dense and confluent. Biopsy is often the only way to make the differentiation. Foci of mesenteric and omental calcifications can also be seen in patients with metastatic mucinous ovarian and gastrointestinal tract neoplasms. Finally, calcified lymph nodes, generally rim-calcified, can be seen, often with an obscure cause. These are considered benign in most cases.

Summary

Magnetic resonance imaging (MRI) of the gastrointestinal tract takes advantage of the inherent outstanding soft tissue contrast of MRI to provide excellent depiction of inflammatory, infectious, ischemic, and neoplastic gastrointestinal diseases. By combining fast imaging pulse sequences with intraluminal and intravenous (IV) contrast agents, MRI can show the normal and diseased bowel wall as well as adjacent inflammatory and neoplastic changes involving the mesentery, peritoneum, and omentum.¹⁻⁵

Imaging the gastrointestinal tract presents significant challenges that can be met with current MRI techniques. In the past, slower MR pulse sequences required several minutes to acquire, resulting in degraded image quality because of bowel peristalsis and respiratory motion. Current high-field MR scanning represents a confluence of hardware and software development that has resulted in fast MRI scans, obtained in a few seconds. Breath-hold precontrast and dynamic breath-hold, contrast-enhanced MRI of the abdomen and pelvis can easily be performed, with outstanding image quality.

Extracellular IV MR contrast agents are relatively inexpensive and have a long track record of safety and efficacy for evaluating abdominal diseases. Intraluminal contrast agents can be administered using over-the-counter (OTC) agents or commercially available oral contrast material.

Protocols for Magnetic Resonance Imaging of the Gastrointestinal Tract

MRI of the gastrointestinal (GI) tract uses rapid breath-hold acquisitions to minimize motion artifacts. Each manufacturer

has pulse sequences available that can be optimized for MRI of the GI tract. Although they have different acronyms, similar pulse sequences and image types are available on scanners from all the major MR manufacturers. The specific pulse sequence parameters, however, will be vendor-specific.

For a general evaluation of the GI tract, we use breath-hold, single-shot (SS) rapid acquisition with relaxation enhancement (RARE) imaging in the axial and coronal planes.¹⁻³ This pulse sequence is known by a number of different acronyms, including single-shot fast spin-echo (SSFSE), single-shot turbo spin-echo (SSTSE), and half-Fourier acquisition single-shot turbo SE (HASTE). These single-slice images are breathing-independent and are thus insensitive to respiratory or peristaltic motion. They provide heavily T2-weighted images and an excellent overall abdominal and pelvic survey. Water-soluble intraluminal contrast material demonstrates high signal intensity, whereas the bowel wall is depicted as a thin, intermediate signal intensity line surrounding the bowel contents. Intestinal mural thickening is depicted on single-shot RARE images when the bowel wall measures more than 3 mm. Single-shot images are obtained without fat suppression.

Unenhanced T1-weighted images depict anatomic structures. 2D or 3D spoiled gradient-echo T1 sequences can be obtained with simultaneous acquisition of in-phase and opposed-phase images. Newer Dixon T1 sequences apply Dixon fat and water separation to the 3D gradient echo images, providing in-phase, opposed-phase, fat-only, and water-only images in a single breath-hold. The Dixon water image provides a precontrast fat-suppressed image that can be compared to the dynamic postcontrast images to assess inflammatory or malignant bowel wall enhancement. Depending on the vendor, Dixon MR sequences are known by the acronyms LAVA-Flex, m-Dixon, and 2-point Dixon.

Fat-suppressed, T2-weighted, fast spin-echo (FSE) images are obtained to distinguish intestinal mural edema from fibrosis. This important distinction may assist in differentiating an acute inflammatory process with wall thickening from a thickened wall caused by a chronic fibrotic stricture. An acute inflammatory stricture will show high signal intensity edema in the thickened bowel wall, whereas the thickened fibrotic wall of a chronic stricture will demonstrate low signal intensity. Fat-suppressed, T2-weighted images may be obtained with breath-holding or with respiratory triggering.

Diffusion-weighted imaging (DWI) uses fast, single-shot echo planar sequences, which are sensitive to the microscopic movement of water protons. Many benign and malignant diseases are characterized by restriction of diffusion and are displayed as areas of altered signal on DWI. DWI has become an integral part of body MRI protocols and is essential for GI imaging. The DWI sequence may be obtained during breath-holding or free breathing, or may be combined with respiratory

triggering. For GI imaging, an intermediate B value of 400 to 500 s/m² provides images with a good balance between adequate diffusion weighting and reasonable anatomic depiction. Higher B values will increase diffusion weighting at the expense of the image signal-to-noise ratio (SNR) and anatomic depiction. DW images are characterized by a high target to background signal, so that diseased bowel is seen with high contrast and conspicuity compared with the relatively suppressed background tissue and intraluminal contents.

Diffusion-weighted images may be displayed as a magnitude image, which is a combination of diffusion signal and T2-shine through, or as an apparent diffusion coefficient (ADC) map. On the ADC map, the T2 component of the image signal is removed so that only areas of true restricted diffusion are displayed. Quantitative measurements of ADC values on these images requires obtaining two or more different B values. I currently acquire three B values, at 20, 500, and 800 s/m². Quantitative measurements of ADC values may be useful to characterize GI masses and monitor the response of tumors to therapy.

Another sequence commonly used for GI tract imaging is balanced, steady-state free precession (SSFP) sequences.⁶ The image contrast is determined by T2* and T1 properties, depending heavily on repetition time (TR). The speed and relative motion insensitivity of this acquisition are useful features for GI imaging. On the balanced SSFP images, water-soluble intraluminal contrast material, blood, bile, ascites, and urine will all demonstrate high signal intensity.

Vendor acronyms for this pulse sequence include balanced turbo field-echo (b-TFE), and fast imaging employing steady-state acquisition (FIESTA), and true fast imaging with steady-state precession (true FISP). The balanced SSFP images show excellent homogeneity of luminal signal and visualization of the normal and diseased bowel wall. Compared to 3D gradient-echo images, the balanced SSFP images are less sensitive to motion artifact but show increased sensitivity to chemical shift and susceptibility artifacts.

Following the IV injection of gadolinium, two sets of axial, fat-suppressed, gradient-echo MR images are obtained through the abdomen and pelvis.⁴ One may use 2D or 3D gradient-echo imaging. The 2D gradient-echo images use a thicker slice thickness of 8 to 10 mm but are typically sharper and have a greater range of contrast than 3D gradient-echo images. The 3D images have a thinner slice thickness and provide more efficient coverage of the abdomen and pelvis. A typical slice thickness for 3D images is 4 mm. Some 3D acquisitions incorporate a fixed or variable slice overlap. The newer 3D Dixon sequences may be used for dynamic postcontrast imaging. The Dixon water image provides very homogeneous fat suppression, with higher SNR and reduced susceptibility artifact.

Water-soluble intraluminal contrast material demonstrates low signal intensity on the fat-suppressed, gadolinium-enhanced (GE) MR images. The bowel wall is shown as rings or lines surrounding the bowel lumen. The thickness of the normal bowel wall is 3 mm or less. The normal bowel wall will show gadolinium enhancement equal to or less than that of the liver parenchyma. Abnormal mural thickening or enhancement can be evaluated as signs of inflammatory or neoplastic intestinal disease.

Important features of the optimized GE MR image include fat suppression, image homogeneity, high-n plane resolution, and breath-hold imaging. In practice, we combine dynamic 3D gradient-echo imaging in the axial plane followed by coronal

and sagittal 3D GE imaging and delayed 2D gradient-echo imaging. The delayed 2D gradient-echo images are often most useful for depicting intestinal mural disease and adjacent disease of the peritoneum, showing excellent image sharpness and contrast conspicuity. The 2D images are also less susceptible to breathing artifacts, which may be more common at the end of the examination.

This MR examination of the GI tract can be performed in 20 to 25 minutes. Specific imaging parameters are listed in Table 6-1.

Coil Selection

Coil selection will depend on the availability of surface coils for a specific MR scanner. Dedicated surface coils, with larger areas of anatomic coverage, are now routinely available from all vendors. I typically require 48-cm coverage in the craniocaudal direction when imaging the abdomen and pelvis. There are now surface coils available that provide this extensive coverage, allowing for combined abdominal and pelvic imaging. One should be careful not to sacrifice image homogeneity when using a dedicated surface coil. Inhomogeneous images can create problems when assessing subtle GI tract or peritoneal disease. Some form of intensity correction algorithm should be used to maximize the homogeneity of the images. Ultimately, phased-array surface coils combined with parallel imaging provides optimal signal and speed of image acquisition.

Patient Preparation and Intraluminal Contrast Material

CONTRAST AGENTS

All patients are asked not to eat or drink for the 4 hours prior to their MRI appointment. If rectal water is to be administered, patients administer a Fleet's enema prior to the examination. If more thorough bowel cleansing is desired, patients are also asked to have a clear liquid diet starting for 12 hours prior to the MRI examination and to take four bisacodyl tablets orally the evening prior to the appointment.

The use of intraluminal contrast material is an essential element of the MRI protocol for GI tract imaging.^{4,7-16} Oral and/or rectal contrast material will distend the stomach, small intestines, and colon, improving the depiction of inflammatory or neoplastic mural disease. Subtle mural thickening can be easily masked by collapsed segments of bowel. Alternatively, incompletely distended bowel can mimic diseased bowel with apparent mural thickening, which will disappear when the bowel is adequately distended. In addition, well-distended bowel facilitates the depiction of an adjacent peritoneal, serosal, or omental tumor.

In my experience, a biphasic intraluminal contrast agent is optimal for GI tract imaging (Fig. 6-1). Water is the classic biphasic MR intraluminal agent, showing high signal intensity on T2-weighted images and low signal intensity on T1-weighted images. On fat-suppressed, GE T1-weighted spoiled gradient-echo (SGE) images, the water-soluble contrast material is low in signal intensity. This allows one to depict the normal bowel wall as a thin, linear, mildly enhancing structure surrounding the dark bowel lumen. Water can be used as an oral contrast agent. However, because water is absorbed through the small intestinal wall, its use as an oral agent for MRI often results in

Figure 6-1 Oral contrast material. Coronal single-shot turbo spin-echo (SSTSE) (A) and gadolinium-enhanced 3D MR images (B) were obtained following oral administration of 1.5 L of Metamucil mixed with water. The water-soluble intraluminal contrast material demonstrates high signal intensity on the T2-weighted SSTSE images (arrow in A) and low signal intensity on the T1-weighted, 3D gradient-echo images (arrow in B).

unpredictable distention of the distal small bowel. For this reason, water-soluble contrast agents that are iso-osmolar are preferred because the ingested contrast will remain in the intestinal tract. In my practice, I have used different intraluminal agents for MRI. All the agents produce a biphasic appearance on MR images; they are readily available and relatively inexpensive. Other commercially available oral agents for MRI containing iron oxides and manganese have been described, but are not currently used in my practice.¹⁴⁻¹⁶

Dilute Barium Sulfate

Barium sulfate solution (Readi-CAT 2, Bracco Diagnostics, Monroe Township, NJ) is composed of 98% water and 2% barium and other additives. On MR images, dilute barium sulfate has a biphasic appearance, with low signal on T1-weighted images and high signal on T2-weighted images. Readi-CAT 2 is commonly used for helical CT scans of the abdomen and pelvis. Dilute barium sulfate will remain within the intestines and is very effective in distending the small bowel and colon. Patients

ingest 300 to 400 mL dilute barium, starting 1 hour before the MRI examination.^{4,5,7} Flavored versions of dilute barium sulfate (Readi-CAT 2 Smoothie, Bracco Diagnostics) are available and may be preferred by some patients.

Psyllium Fiber Mixed with Water

This is another water-soluble contrast agent that produces a biphasic appearance on T1-weighted and T2-weighted images (see Fig. 6-1).^{8,9} Metamucil (Proctor & Gamble, Cincinnati) is composed of psyllium fiber with orange flavoring. It is a dietary fiber supplement that can be purchased over the counter. Its active ingredient is psyllium husk, a natural plant fiber with a high percentage of soluble fiber. Because Metamucil is orange-flavored, it is typically preferred by patients and better tolerated than dilute barium sulfate. A total dose of 0.8 mg/kg body weight Metamucil is mixed in 1 to 1.5 L of water. I mix a half-scoop of Metamucil per 8-ounce glass of water and have patients ingest four or five glasses over 1 hour prior to the examination. To improve filling of the distal small bowel, I have patients drink two of the glasses of Metamucil at home before leaving for their appointment. Unlike the Readi-CAT 2, some of the water in the Metamucil is absorbed in the small intestine and will be excreted via the kidney.

VoLumen

VoLumen (Bracco Diagnostics) is a low-density barium sulfate contrast agent especially designed for MDCT (multidetector computed tomography), positron emission tomography (PET), and CT examinations to mark the bowel as a negative intraluminal contrast agent. It is an ultra-low-dose barium sulfate agent with only 10% of the barium sulfate of conventional CT barium oral contrast agents. With VoLumen, 0.1% with barium is combined with 3% sorbitol, a nonabsorbable sugar alcohol that promotes luminal distention and limits the resorption of water across the length of the small bowel. VoLumen can be used for MRI of the GI tract, providing a biphasic appearance similar to that obtained with dilute barium sulfate. Theoretical advantages of VoLumen might include better bowel distention and more rapid bowel transit because of the sorbitol.

I am unaware of any direct comparisons. In my experience, the degree of bowel distention is related more to the volume and timing of the administration of the oral contrast material.

Mannitol 2.5% Mixed with 2% Locust Bean Gum

This has been proposed as an effective iso-osmolar, water-soluble oral agent for MRI.^{10,11} Mannitol is a white, crystalline, water-soluble, slightly sweet alcohol, $C_6H_8(OH)_6$, used as a dietary supplement and dietetic sweetener. Mannitol comes in 500-mL bags mixed to a concentration of 20%. Mannitol 2.5% can be prepared by mixing 187.5 mL of 20% mannitol with enough tap water to achieve a volume of 1.5 L, and 3 g of locust bean gum (2%) is added to the mannitol solution to slow down the transit time through the intestinal tract. Locust bean gum, also called carob bean gum and Carubin, is extracted from the seed of the carob tree. It is used in ice cream, cultured dairy products, and cream cheese. The locust bean gum has been reported to decrease the diarrhea produced by orally ingested mannitol. The 1.5-L, 2.5% mannitol solution with locust bean gum is ingested over 1 hour prior to the MR examination. Sorbitol 2% can be used as an alternative to mannitol.¹⁰

Rectal Water

This can be administered to distend the rectum and colon. I administer 500 to 1000 mL of tap water through a balloon-tipped barium enema catheter. Slow administration will help maximize the amount of fluid tolerated by the patient. The balloon at the tip of the catheter should be filled with water to avoid the susceptibility artifact caused by air in the balloon.

ROUTES OF CONTRAST ADMINISTRATION

Intraluminal contrast material can be administered orally, with patients drinking 1 to 1.5 L of contrast material over 1 hour prior to the examination. Alternatively, contrast may be administered via a nasojunal tube, as has been described for CT and MR enteroclysis. The enteroclysis technique has the advantage of more controlled and consistent small bowel distention but obviously requires nasojunal intubation.¹⁷⁻¹⁹ Oral administration of intraluminal contrast material is effective in cooperative patients and can be combined with rectally administered water for simultaneous evaluation of the small bowel and colon.

ANTIPERISTALTIC AGENTS

Contrast-enhanced 3D GE images can be degraded by motion artifact related to bowel peristalsis. An antiperistaltic drug can markedly improve image quality. Glucagon, 1 mg, can be administered IV at the time of gadolinium injection. An alternative approach is to administer 0.25 mg hyoscyamine (Levsin) IV prior to the start of the examination. Levsin has a slower onset of action and longer duration compared with glucagon. In Europe, butylscopolamine (Buscopan) is commonly used to reduce bowel peristalsis. Users should consult the package insert to review contraindications prior to drug administration.

Clinical Applications

INFLAMMATORY BOWEL DISEASE

Crohn's Disease

MRI provides many unique advantages when evaluating the mural changes of Crohn's disease.^{7,20,21} Distending the bowel lumen with water-soluble contrast material allows one to depict the diseased bowel wall in the patient with active Crohn's disease. On MR images, one may assess the thickness of the bowel wall, its degree and pattern of enhancement, and presence of adjacent mesenteric inflammation. MDCT is equally effective in assessing bowel wall thickening but is more limited in its assessment of mural enhancement. Compared with MDCT, the degree of bowel wall enhancement is much more conspicuous on GE MRI. This marked enhancement of inflamed bowel segments on 2D or 3D GE MR images facilitates the detection of subtle Crohn's disease. A wall thickness greater than 3 mm is abnormal in a well-distended segment of bowel. Bowel wall thickening can be assessed on SS RARE images or fat-suppressed GE images.

Crohn's Disease Activity. Determining the activity of Crohn's disease has important clinical implications that affect the selection of appropriate treatment options. Patients with recurrent abdominal pain because of active Crohn's disease require treatment. However, patients commonly present with

symptoms that may be unrelated to reactivation of their Crohn's disease. This latter group of patients requires entirely different management. The activity of Crohn's disease may be determined from clinical parameters, including the Crohn's disease activity index, an assessment of acute-phase reactants (e.g., white blood cells [WBCs], erythrocyte sedimentation rate, C-reactive protein, orosomucoids), or clinical symptoms and physical findings. In practice, these clinical parameters may be misleading or inconclusive. The results of endoscopy and imaging studies can play an important role in determining the activity and extent of Crohn's disease.

The activity of Crohn's disease can be assessed by a number of different MRI parameters, including degree of bowel wall enhancement, pattern of enhancement, thickness and length of the involved diseased segment, and presence of edema in the bowel wall on T2-weighted images. Restricted diffusion within the diseased segments of bowel also indicates active inflammation. Perienteric changes, including enhancing lymph nodes, infiltration of mesenteric fat, and increased mesenteric vascularity, can also reflect active Crohn's disease.^{7,20-23}

Degree of Bowel Wall Enhancement. The degree of mural enhancement with IV gadolinium correlates with the activity of Crohn's disease.⁷ Enhancement of the thickened bowel wall can be assessed on the first set of GE images by comparing the bowel wall enhancement to the liver and intravascular gadolinium. The normal bowel wall enhances less than the liver parenchyma. Mural enhancement of thickened bowel greater than that of

the liver is abnormal, and mural enhancement equal to that of intravascular gadolinium is markedly abnormal. In chronic inactive Crohn's disease, the thickened bowel wall will show no enhancement or only mild enhancement (Fig. 6-2). Chronic fibrotic strictures will show a thickened bowel wall with minimal enhancement. Active Crohn's disease shows moderate to marked bowel wall enhancement (Fig. 6-3). In patients with a layered pattern of enhancement (see later), the enhancing mucosa should show moderate to marked enhancement.

Pattern of Bowel Wall Enhancement. A layered pattern of mural enhancement indicates active Crohn's inflammation (Fig. 6-4).²³ One will see marked mucosal and serosal enhancement with an intervening nonenhancing layer representing an edematous bowel wall. In one study, this layered pattern of mural enhancement was present in 7 of 24 bowel segments with active Crohn's disease and in no segments with inactive disease.²³ Full-thickness or diffuse enhancement of the thickened bowel wall will also represent active Crohn's disease if there is moderate to marked mural enhancement. Diffuse enhancement is the most common pattern of mural enhancement in active Crohn's disease. Mild diffuse enhancement can be seen in bowel segments with inactive Crohn's disease.

T2-Weighted Appearance of the Bowel Wall. Active Crohn's disease may show a high signal in the thickened bowel wall, indicating bowel wall edema and inflammation.²⁰ Chronic inactive Crohn's disease will show a less intense signal in the thickened bowel wall, usually equal to or less than that of muscle. A

Figure 6-2 Inactive Crohn's disease. **A.** Axial single-shot fast spin-echo (SSFSE) image shows distal ileum with mural thickening (arrow). Note the low signal intensity of the thickening bowel wall. **B.** Immediate gadolinium-enhanced SGE image shows minimal enhancement of the thickened bowel wall (arrow). Absence of perienteric inflammation and stranding is also noted. Findings correlate with inactive Crohn's disease, which was confirmed at endoscopy.

Figure 6-3 Active Crohn's disease with marked mural enhancement. **A.** Axial gadolinium-enhanced 3D GE image shows an abnormal terminal ileum (arrow) with moderate mural thickening and marked enhancement. The degree of enhancement indicates active Crohn's disease. **B.** Coronal MR hydrogram shows a stricture (arrow) of the terminal ileum.

Figure 6-4 Active Crohn's disease with layered pattern of enhancement. **A.** Immediate axial gadolinium-enhanced 3D gradient-echo (GE) image shows an abnormally thickened terminal ileum (arrow) with a layered pattern of enhancement. **B.** Coronal gadolinium-enhanced 3D GE image confirms the diseased terminal ileum (short white arrow) and shows associated findings of acute Crohn's disease, including enhancing mesenteric lymph nodes (long white arrow) and mesenteric stranding (black arrow). **C.** Endoscopic view of the terminal ileum confirms active Crohn's disease, with mucosal inflammation (arrow).

fibrotic stricture can show a very low mural signal, similar to the psoas muscle. Fat-suppressed T2-weighted images are most useful to assess the signal intensity of the diseased segments of bowel. SS RARE images are useful for showing the segments of bowel but are less sensitive to the presence of bowel wall edema.

Diffusion-Weighted Imaging. Diffusion-weighted images obtained with an intermediate B value of 500 s/m² demonstrate restricted diffusion within the wall of diseased segments of bowel. The abnormal mural signal is demonstrated as areas of hyperintensity on magnitude DWI images or as areas of decreased signal on ADC maps. In my experience, this finding of restricted diffusion suggests active mural inflammation, which will resolve with effective therapy. Conversely, lack of restricted diffusion and mural edema on T2-weighted images indicate chronic disease without active inflammation.

Bowel Wall Thickness. In general, segments of bowel with active Crohn's disease will show greater mural thickness than segments with inactive disease.^{7,20,23} This assessment is affected by the degree of luminal distention. In one study, the mean thickness of segments with active Crohn's disease was 6.7 mm compared with 3.3 mm for segments with inactive disease. However, significant overlap exists between the mural thickness of the active and inactive groups.²³ Fibrotic strictures without active inflammation may show a moderately thickened bowel wall. In these cases, absence of moderate or marked mural enhancement will help characterize this as a chronic process, without active inflammation.⁷

Mesenteric Stranding. Infiltration of the adjacent mesentery and "whiskering" of the bowel wall are indirect indications of active Crohn's disease (see Fig. 6-4). This finding may be depicted on SS RARE images, true fast imaging with steady-state precession (FISP) images, or fat-suppressed, GE gradient-echo images as a linear signal or enhancement extending from the inflamed bowel into the adjacent small bowel or colonic mesentery.^{22,23}

Increased Mesenteric Vascularity. The vessels of the vasa recta supply the small bowel or colon. Increased prominence of the size and/or number of mesenteric vessels in the vasa recta can be an indication of active inflammation. In one study, increased mesenteric vascularity was present in 18 of 23 patients with active disease and 3 of 7 patients with inactive disease.²³

Enhancement of Mesenteric Lymph Nodes. Gadolinium enhancement of mesenteric lymph nodes is another strong indicator of active Crohn's disease (see Fig. 6-4).²² When comparing nodal signal intensity with that of adjacent fat, an enhancement ratio of 1:3 has been found to be a sensitive marker for active Crohn's disease. Mesenteric lymph nodes in patients with inactive Crohn's disease will not show significant enhancement. Lymph nodes are most conspicuous on diffusion-weighted images.

Monitoring Response to Treatment. Following patients with Crohn's disease on serial MR examinations is preferred to avoid the cumulative radiation exposure from repeated CT scanning.

Figure 6-5 Crohn's disease. Response to therapy. Serial coronal (A) and axial (B) 3D GE gadolinium-enhanced images were obtained in 2005 (left), 2007 (middle), and 2009 (right). Inflammatory changes (arrows) in the right lower quadrant in 2005 show progressive resolution of serial follow-up examinations. **C.** Serial diffusion-weighted images, B value of 500 s/m², show initial large area of restricted diffusion in the right lower quadrant (2005) that resolved on subsequent examinations in 2007 and 2009.

With effective therapy, MR images of the diseased bowel segment demonstrate decreased restricted diffusion, decreased enhancement, and decreased mural edema on T2-weighted images (Fig. 6-5). Resolution of perienteric changes is also seen. Conversely, with relapse and recurrence of active inflammation, MR images show a reappearance of these same findings (Fig. 6-6). Therefore the findings on MRI will disappear and then reappear as they reflect response to treatment and subsequent recurrence of disease. This multiparametric approach to monitoring disease status on MRI allows one to distinguish segments of bowel with active inflammation from those with chronic disease and to characterize chronic fibrotic strictures with superimposed active inflammation accurately.

Complications of Crohn's Disease. Perienteric complications of Crohn's disease include abscess or phlegmon formation and fistulas. Abscesses are depicted on MR images as extraintestinal fluid collections, with a surrounding thick, enhancing abscess wall.⁷ Following administration of water-soluble intraluminal contrast material, the fluid content of an abscess may be

difficult to distinguish from bowel contents on T1- or T2-weighted images. However, on fat-suppressed GE MR images, the thick, enhancing abscess wall is easy to identify. The marked degree of enhancement of the abscess wall with gadolinium often makes the abscess easier to detect on MR images than on helical CT scans using iodinated contrast material (Fig. 6-7).

The development of fistulas in Crohn's disease is a common complication; it presents as abnormal connections between the diseased bowel and other organs or the skin. Enterointestinal fistulas occur between segments of bowel, whereas enterocutaneous fistulas occur between diseased bowel and the skin surface. Enterovesicular fistulas communicating with the bladder and enterovaginal fistulas extending from diseased intestines to the vagina are common complications of pelvic Crohn's disease.

With MRI, Crohn's fistulas are depicted as fluid- or air-containing tracts on fat-suppressed, T2-weighted images or as enhancing tracts on fat-suppressed, GE gradient-echo MR images.²⁴ High-resolution surface coil imaging with thin-section, short tau inversion recovery (STIR) or 3D GE images

Figure 6-6 Crohn's disease recurrence (same patient as in Fig. 6-5). On a follow-up MR examination in 2012, the coronal (A) and axial (B) 3D GE gadolinium-enhanced images show interval recurrence of the right lower quadrant inflammatory changes (arrows). (C) A DWI, B value of 500 s/m², shows recurrence of the restricted diffusion (arrow) in the right lower quadrant.

are most useful to depict the fistulous communication. The accurate depiction of Crohn's fistulas is important when selecting patients for anti-tumor necrosis factor (TNF) therapy. Infliximab (Remicade) blocks the immune system's overproduction of a protein (TNF- α), with subsequent reduction in draining enterocutaneous and rectovaginal fistulas.

Ulcerative Colitis

Ulcerative colitis is depicted by MRI with colonic mural thickening and enhancement.²⁵ Unlike Crohn's disease, which can be discontinuous, with skip areas, ulcerative colitis is a continuous process that always begins in the distal colon and rectum and progresses proximally. Although the inflammation of ulcerative colitis should only involve the mucosa and submucosa, on MRI scans the entire colonic wall is thickened and shows enhancement. It is possible that with higher resolution MRI, combined with rapid and earlier dynamic imaging, one may be able to distinguish the superficial inflammatory changes of ulcerative colitis from the transmural inflammation of Crohn's disease. With current techniques, Crohn's disease with continuous pancolitis has a very similar appearance to that of ulcerative colitis.

Perirectal and perianal complications of ulcerative colitis include fistulas and abscess formation. Surface coil images of

the rectum can be obtained using thin-section images angled perpendicularly and parallel to the rectum and perianal area. Fat-suppressed STIR images and thin-section, 3D GE images are particularly useful to evaluate this anatomic region. Fistulous tracts will be depicted as high-signal linear tracts on the STIR images or as linear enhancing tracts extending between diseased bowel and adjacent structures on 2D or 3D GE images. An abscess will be shown as a pericolic or perirectal fluid collection, with an enhancing abscess wall. Surrounding inflammation will show similar enhancement with intravenous (IV) gadolinium.

INFECTIOUS BOWEL DISEASE

Infectious disease involving the stomach, small intestine, or colon may be caused by bacterial, viral, or parasitic organisms. Infectious enteritis or colitis will be depicted as segments of bowel with mural thickening and enhancement that are indistinguishable from those of inflammatory bowel disease. The infectious disease may be focal or may involve long segments of the small intestine or colon. Associated infiltration of the perintestinal fat is depicted as linear strands extending from the diseased bowel into the adjacent mesenteric fat on SS RARE and

Figure 6-7 Crohn's phlegmon and abscess. **A.** Axial SSFSE image shows an abnormal small bowel (short white arrow) and a heterogeneous mass (long white arrow) in the right lower quadrant. **B.** Axial gadolinium-enhanced SGE image depicts a markedly enhancing phlegmon and central, nonenhancing abscess (arrow). **C.** Coronal gadolinium-enhanced SGE image confirms the thickened and enhancing terminal ileum (arrow). **D.** Endoscopic view of the terminal ileum shows a nodular inflamed mucosa. Biopsy confirmed active inflammation of Crohn's disease.

Figure 6-8 Infectious ileitis. **A.** Helical CT scan through the middle abdomen is unremarkable. **B.** GE fat-suppressed, SGE MR image with oral contrast material shows abnormally thickened and enhancing ileum (arrows) in the right side of the abdomen. MRI, the patient was treated for an infectious ileitis, with good clinical response.

fat-suppressed GE images. In the acute phase, there is marked mural enhancement of the diseased small bowel or colon (Fig. 6-8). Complications, including peri-intestinal abscess or phlegmon, are depicted on MR images as adjacent fluid collections with an enhancing abscess wall or as soft tissue inflammatory masses.

Pseudomembranous colitis is caused by *Clostridium difficile*, an anaerobic, gram-positive bacillus. Use of various antibiotics,

including clindamycin, broad-spectrum penicillins, and cephalosporins, alters the normal colonic flora, allowing for overgrowth of *C. difficile*. Toxins produced by pathogenic strains of *C. difficile* produce diarrhea and pseudomembranous colitis. With MRI, pseudomembranous colitis is depicted as marked colonic mural thickening and gadolinium enhancement. The descending and sigmoid colon is typically involved in pseudomembranous colitis. The degree of mural thickening can be

quite marked; the disease typically involves long segments of the colon. The marked mural thickening can help distinguish pseudomembranous colitis from other forms of infectious colitis.

ACUTE APPENDICITIS

Acute appendicitis can be depicted with MRI. The thick-walled, enlarged appendix shows moderate to marked enhancement on fat-suppressed GE MRI scans. DWIs show restricted diffusion within the abnormal appendix (Fig. 6-9). Fat-suppressed, T2-weighted images may show edema—ascites in the right lower quadrant. I do not use oral or rectal contrast in the clinical setting of suspected appendicitis. Additional thin-section, non-fat-suppressed, FSE T2-weighted images are obtained in the axial and coronal planes through the region of the appendix.

ISCHEMIC BOWEL DISEASE

Acute or chronic mesenteric ischemia is caused by insufficient blood supply through the mesenteric circulation supplying the GI tract. Chronic mesenteric ischemia develops slowly as a late-stage complication of atherosclerotic disease producing classic

so-called intestinal angina, with postprandial abdominal discomfort. Acute mesenteric ischemia results from a sudden decrease in mesenteric blood flow and is potentially life-threatening.

One may combine GE 3D MR angiography with anatomic images of the abdomen and pelvis.²⁶⁻³⁰ This approach allows one to visualize the mesenteric arteries directly and assess the small bowel and colon for secondary changes of mesenteric ischemia. In my experience, it is more common to see the secondary bowel wall changes with mural thickening and altered enhancement. In patients with acute arterial insufficiency, there will be diminished or absent enhancement within the thickened segments of ischemic bowel (Fig. 6-10). One can also see a layered appearance with mucosal and serosal enhancement but with decreased enhancement of the intervening submucosal and muscularis layers of the bowel wall. In the nonacute setting, the pattern of enhancement will be variable, depending on the degree of revascularization, fibrosis, or tissue necrosis. In my experience, the MRI findings can resolve very rapidly following spontaneous revascularization of the ischemic segment of bowel. An assessment of the degree of mural enhancement should be based on the first arterial phase set of images. On delayed images, the diseased bowel wall may enhance because of leaking, damaged capillaries.

Figure 6-9 Appendicitis. Coronal (A) and axial (B) gadolinium-enhanced 3D images demonstrate a dilated appendix (arrows) with an enhancing thickened wall. C. DWI, B value of 500 s/m², shows an abnormal appendix (arrow) with restricted diffusion.

Figure 6-10 Ischemic colitis.

A. Axial fat-suppressed, gadolinium-enhanced, SGE image shows colonic mural thickening involving the ascending colon (arrow). A layered pattern of enhancement is present, with enhancement of the mucosa and bowel serosa, but without enhancement of the muscularis propria. **B.** Coronal fat-suppressed, GE image shows the distribution of the colitis involving the ascending and transverse colon (arrows). Gadolinium-enhanced MR angiography findings (not shown) were normal. **C.** Endoscopic view shows markedly abnormal mucosa in the ascending colon. Biopsy confirmed changes of ischemic colitis.

GASTROINTESTINAL MALIGNANCY

Stomach

The American Cancer Society estimated that in 2013 there would be 21,600 new cases of gastric cancer diagnosed in the United States, with 11,550 deaths from gastric cancer. The 5-year survival rate in the United States is 27%. Worldwide gastric cancer is the fourth most common cancer.³¹ Early diagnosis and accurate preoperative staging are critical for patient management and treatment.

MRI provides an elegant way to image gastric cancer.³²⁻³⁶ The depth of tumor penetration into the gastric wall can be accurately assessed with high-resolution T2-weighted images and GE MRI scans. Maximal distention of the gastric lumen with water-soluble oral contrast is essential to optimize depiction of the mural thickening or mass. Negative intraluminal agents on fat-suppressed, GE T1-weighted images are desirable because the dark lumen will help highlight the adjacent bowel wall and mural tumors. Large volumes of water or other oral agents should be ingested immediately before scanning. Pharmacologic agents can be administered to decrease peristalsis, but are not essential.

Thin-section, breath-hold, T2-weighted SS RARE images (SSTSE, SSFSE, HASTE), combined with fat-suppressed 3D GE

imaging, is most effective for depicting the transmural tumor extension used for tumor staging. The wall of the normal, well-distended stomach is depicted on unenhanced T1, T2, and SSFSE images as a thin, uniform, hypointense line typically measuring 2 to 3 mm in thickness. Prominent gastric rugal folds can increase the apparent thickness of the stomach wall. On dynamic GE images and delayed equilibrium phase images, the stomach wall will show only mild, uniform, and homogeneous enhancement.

Gastric cancers will be depicted on MR images as areas of focal mural thickening or as mural masses (Fig. 6-11). Superficial gastric cancer may not be visible on cross-sectional imaging. As they grow, they will be depicted as areas of focal mural thickening and eventually as a gastric mass. On dynamic GE MRI, gastric cancers will show more enhancement than the adjacent normal gastric wall. The presence of focal gastric mural thickening with a pattern of rapid enhancement is suggestive of gastric cancer. Linitis plastica will be depicted as a nondistensible stomach with a thickened, enhancing wall.

Transmural tumor invasion by a T3 or T4 tumor is indicated by disruption of this low-signal intensity band overlying the mural tumor, nodular tumor, or enhancing tumor masses and extending from the gastric wall into the surrounding perigastric fat.

Figure 6-11 Gastric cancer. Coronal SSTSE image (A) and gadolinium-enhanced 3D image (B) demonstrate moderate mural thickening of the distal gastric body and antrum (arrows). Ascites is also present. Note the distention of the gastric lumen with water, facilitating depiction of the mural thickening. Gastric cancer was confirmed at endoscopy and biopsy.

Nodal metastases are best shown on fat-suppressed T2-weighted images or DWI using a B value of 500 s/mm². In my experience, DWI is the most sensitive modality for depicting lymphadenopathy. Liver metastases are best shown on T1- and T2-weighted imaging and dynamic GE imaging. Peritoneal metastases commonly occur with GI malignancies and are best visualized on delayed, fat-suppressed, GE images. Osseous metastases can be visualized as high-signal intensity lesions on fat-suppressed T2-weighted images or as enhancing lesions on fat-suppressed GE images.

Small Intestine

Cancer arising in the small intestine is an uncommon malignancy, accounting for 2% of GI cancers. Cancer arising in the colon is 50 times more common than small bowel cancer. In the United States, the American Cancer Society estimated 8810 new cases of small bowel cancer in 2013, with 1070 associated deaths.³² Adenocarcinoma is the most common cell type, accounting for about one third of small bowel cancers. Other small bowel cancers include carcinoid tumors, leiomyosarcomas, and lymphomas.^{37,38}

Bowel distention is essential for MRI of small intestinal cancer. Intraluminal contrast may be administered orally with any of the oral contrast agents described earlier. Alternatively, small bowel enteroclysis may be performed with intraluminal contrast material infused through a nasojejunal tube providing maximal small bowel distention. On breath-hold SS FSE and fat-suppressed GE imaging, small bowel cancers will be depicted as areas of small intestinal mural thickening and masses. Because of their late clinical presentation, small bowel tumors are typically large tumor masses. Associated small bowel obstruction is indicated by distended loops of fluid-filled small bowel proximal to the obstructing mass.

Semelka and colleagues have described the appearance of small bowel tumors on MRI,³⁷ noting that small bowel tumors are isointense to small bowel on T1-weighted images. Malignant tumors showed moderate heterogeneous enhancement greater than that of the adjacent normal bowel on GE SGE imaging. Unenhanced T1-weighted and fat-suppressed, GE imaging are best for depicting tumor extent.

Colon and Rectum

Colorectal Cancer. Colorectal cancer is the third most commonly diagnosed malignancy in the United States and is the

second leading cause of cancer-related deaths. The American Cancer Society estimated that there would be about 142,820 new cases of colorectal cancer in 2013 in the United States, with an estimated 50,830 deaths.³⁹ The role of MRI for preoperative staging of colorectal cancer is well established and has been described in multiple studies.⁴⁰⁻⁵⁶

Different techniques have been proposed for MRI of colorectal cancer.⁴¹⁻⁴⁹ Endorectal coils or phased-array surface coils have been used to increase spatial resolution while maintaining an adequate SNR.⁴⁹⁻⁵¹ Some authors have advocated using positive or negative intraluminal contrast agents administered rectally to distend the rectosigmoid colon.⁵³⁻⁵⁵ In addition to the routine MR examination of the abdomen and pelvis described earlier, specific imaging sequences are used in the patient with colorectal cancer to assess local tumor extent and regional or distant metastases.

Thin-Section, High-Resolution, Angled T2-Weighted Turbo Spin-Echo Magnetic Resonance Imaging. High-resolution, phased-array surface coil images of rectal or colon cancer are obtained using thin-section, T2-weighted FSE images oriented perpendicularly and parallel to the cancer (Fig. 6-12).⁴¹⁻⁴³ These angled, T2-weighted images are prescribed from the sagittal T2-weighted images of the pelvis. Specific parameters for a rectal cancer MR protocol is shown in Table 6-2. These angled, T2-weighted images use a smaller field of view (FOV) and 3- to 4-mm slice thickness for detailed, high-resolution imaging of the rectal cancer. Higher signal averages combined with the phased-array surface coils are used to maintain an image SNR. Motion-corrected versions of the T2-weighted FSE sequences are available; these can reduce artifacts from patient or bowel motion. The motion-corrected sequences are known by the acronyms Propeller, Blade, Multivane, RADAR, and JET and are available from several different vendors.

Thin-section images are most useful for tumor staging, determining the depth of tumor penetration into the wall of the rectum or colon. The muscularis propria is easily depicted as a thin, low signal intensity linear structure. Disruption of the muscularis propria by tumor is evidence of T3 cancer, with transmural tumor extension. One may also use thinner slice sections (3 mm) with a smaller FOV by increasing the number of signal averages (NSA) to 8, with a corresponding increase in acquisition time.

Diffusion-Weighted Magnetic Resonance Imaging. I also use diffusion-weighted MRI (DW MRI) to evaluate colon and rectal

Figure 6-12 Rectal cancer. Coronal (A) and axial (B) surface coil, T2-weighted MR images angled parallel and perpendicular to rectal cancer depict a T3 rectal cancer (arrows) with extramural tumor extension. C. Axial gadolinium-enhanced SGE image shows the irregular rectal mass (arrows). D. Follow-up MRI scan obtained after chemotherapy shows response to treatment, with marked decrease in the rectal cancer (arrows).

cancers. GI tract cancers show marked hyperintensity on diffusion-weighted images, improving their conspicuity (see Fig. 6-12).⁵⁷⁻⁶⁰ DW images are also very useful for the nodal staging of colon and rectal cancer. Small perirectal and pericolic nodal metastases are markedly hyperintense on DW images, facilitating their depiction (see Fig. 6-13). In patients

with locally advanced rectal cancer, the addition of DW MRI to conventional MRI can improve the depiction of tumor response to adjuvant chemotherapy and radiation therapy. Malignant gastrointestinal tract tumors have low ADC values, which increase after successful therapy.

I typically use a B value of 500 s/m² for extrahepatic DW imaging. With this B value, anatomic landmarks are still visible, whereas most intestinal fluid and ascites are suppressed. Specific MRI parameters for DWI are shown in Table 6-3.

Magnetic Resonance Staging of Colorectal Cancer. Preoperative MRI of colon and rectal cancers effectively determines local tumor extension, nodal metastases, and distant abdominal metastases.⁴¹⁻⁴⁹ These three features form the basis of TNM tumor staging. Stage I colon cancers are any T1 or T2 tumors without nodal or distant metastases. Stage II colon cancers are T3 or T4 tumors without nodal or distant metastases. Stage III colon cancers are any tumor with nodal involvement, and stage IV colon cancers are those with distant metastases. The overall MR staging accuracy for rectal cancer has ranged from 67% to 100%.⁴⁰

The information from preoperative MRI is used to direct patient management. Rectal cancer patients in whom MRI depicts stage III cancers with transmural tumor extension (T3 or T4) or stage IV cancers with nodal metastases undergo preoperative radiation therapy. After radiation therapy, follow-up MRI documents a reduction in tumor volume, resulting in an improved chance for successful surgical resection (see Fig. 6-12). In this scenario, the information from preoperative MRI is critical for directing management decisions of the patient with colorectal cancer.

Local Tumor Extension. Tumor staging determines the depth of mural penetration by the colon or rectal cancer. Tis (tumor in situ) indicates carcinoma in situ, T1 tumors invade the submucosa, T2 tumors invade the muscularis propria, T3 tumors extend through the muscularis propria onto the subserosa or nonperitonealized pericolic or perirectal tissues, and T4 tumors directly invade adjacent organs or structures.

The most challenging assessment is to distinguish T2 from borderline T3 cancers. Peritumoral fibrosis extending into the perirectal fat in a T2 tumor can be difficult to distinguish from early transmural extension from a T3 tumor. On the other

hand, nodular soft tissue extending through the disrupted rectal wall into the surrounding tissues confidently predicts a T3 or T4 cancer.

Nodal Metastases. Node staging is based on the presence or absence of local or regional nodal metastases. Although MRI can depict lymph nodes 2 to 3 mm in diameter, MRI assessment of nodal metastases remains limited to an evaluation of the size and number of lymph nodes (see Fig. 6-13). Morphologic criteria for evaluating lymph nodes pose obvious limitations. Microscopic metastases in normal-sized lymph nodes cannot be detected, and enlarged, inflammatory lymph nodes cannot be distinguished from nodal metastases. The accuracy of the detection of nodal metastases varies from 39% to 95%.⁴⁰ The use of ultrasmall superparamagnetic iron oxide (USPIO) contrast agents for depicting lymph node metastases has shown promise in early reports. The iron particles are phagocytosed by macrophages and taken up by the reticuloendothelial system. Normal lymph nodes will contain macrophages with iron particles and show loss of signal on GE MR images because of a susceptibility effect. Tumor deposits within lymph nodes displace the reticuloendothelial system and show areas of increased signal because of less uptake of the USPIO.

Distant Metastases. Metastasis staging is based on the presence or absence of distant metastases to the liver, peritoneum, mesentery, omentum, bowel serosa, lymph nodes, osseous structures, and lungs (Fig. 6-14).

Circumferential Resection Margin and the Mesorectal Fascia. Although TNM tumor staging provides important information, it is actually more important to determine the circumferential, tumor-free resection margin, which is the distance between the rectal tumor and surrounding mesorectal

Figure 6-13 Diffusion-weighted image of rectal cancer. **A.** Angled T2-weighted image depicts a T3 rectal cancer (arrow). **B.** DWI, B value of 500 s/m², shows marked hyperintensity of the rectal cancer (long arrow) and perirectal lymph node (short arrow). **C.** DWI, B value of 500 s/m², at an adjacent level shows multiple markedly hyperintense nodal metastases (arrows). Findings indicated a stage 3, T3N1M0, rectal cancer.

Figure 6-14 Metastatic colon cancer. **A.** Axial gadolinium-enhanced SGE image shows a heterogeneous enhancing mass (arrow) in the right lower quadrant. **B.** Axial gadolinium-enhanced image through the upper abdomen depicts enhancing right subphrenic peritoneal metastases (white arrows) and left subphrenic peritoneal metastases (black arrow). **C.** Coronal gadolinium-enhanced SGE image shows the mass in the right lower quadrant (black arrow) with associated bowel obstruction. Right subphrenic peritoneal metastases (white arrow) are confirmed. MR findings indicated a stage 4 colon cancer, with bowel obstruction and peritoneal metastases.

fascia.^{50,51} This tumor-free resection margin can be accurately and consistently predicted on high-resolution, phased-array, surface coil MR images.

The mesorectal fascia encloses the mesorectum, an anatomic unit comprised of the rectum, perirectal fat, superior hemorrhoidal vessels, nerves, and lymphatics. At surgery, patients undergo total mesorectal excision, with en bloc resection of the rectal cancer and surrounding tissues enclosed within the mesorectal fascia. This technique has resulted in a decrease in local tumor recurrence. With mesorectal excision, surgical failure resulting in local tumor recurrence is usually because of incomplete removal of the lateral spread of a tumor with microscopically positive resection margins.

Based on the MRI assessment of the circumferential resection margin (CRM), patients can be categorized and treated according to their risk of local recurrence. Superficial tumors may be treated with surgery alone. Operable T3 cancers with a wide CRM are treated with a short course of radiation therapy followed by mesorectal excision. Patients with locally advanced cancer in whom the tumor approaches or involves the resection margin are at greater risk for recurrence and will benefit from a more extended course of radiation therapy and chemotherapy, followed by surgical resection.

In a study of 76 patients with rectal cancer, Beets-Tan and associates evaluated the MRI assessment of the CRM compared with histopathology.⁵⁵ They noted that two observers correctly predicted a 0-mm resection margin in 12 of 12 patients with T4

cancers. In 29 patients with histologic resection margins of 10 mm or less, these observers correctly predicted a 10-mm resection margin in 27 and 28 patients. In a study of 98 patients with rectal cancer, Brown and co-workers reported 92% agreement between MRI and histologic findings for predicting the circumferential resection margin.⁴²

Locally advanced rectal cancers will extend beyond the mesorectal fascia and invade surrounding structures and organs. High-resolution surface coil MRI is more accurate than helical CT for depicting the invasion of adjacent structures by advanced rectal cancers. In one study of 26 patients, MRI had a 97% sensitivity and 98% specificity for local invasion compared with 70% and 85% for helical CT.⁵⁶

Summary

MRI offers unique advantages for evaluating inflammatory, infectious, ischemic, and malignant diseases of the GI tract. By combining readily available intraluminal and IV contrast agents with fast MRI techniques, one can reliably depict the wall of the stomach, small intestine, colon, and rectum. The inherent high-contrast resolution of MRI allows mural disease to be depicted confidently as areas of wall thickening and enhancement. MRI of the GI is a robust and versatile technique that can be applied to a wide variety of benign and malignant gastrointestinal diseases.

Staging

Restaging and Treatment Response

Positron emission tomography (PET) is a molecular imaging modality that has been increasingly used in clinical practice worldwide, especially in the oncologic population. It has gained widespread use for the diagnosis, staging, restaging, and monitoring treatment response of various malignancies.^{1,2} For years, computed tomography (CT), ultrasound (US), and magnetic resonance imaging (MRI) have been used for the detection and follow-up of tumors that grossly rely on the morphology or attenuation characteristics of pathologic tissue. PET has the ability to provide physiologic information by determining metabolic activity at a cellular level at an early phase, which is a shortcoming of cross-sectional imaging modalities. Thus, distinction of malignant versus benign lesions, detection of metabolic activity in organs that are not yet morphologically abnormal, and evaluation of the response of neoplasms to various treatments such as chemotherapy, radiation, or surgery have become possible with the use of PET.

PET imaging uses positron-emitting radionuclides produced in cyclotrons. Once the radiotracer is injected, the positron is emitted into the body. It travels a short distance, loses its energy, and interacts with electrons in tissue. This causes an annihilation reaction, which produces two 511-keV gamma rays that are emitted in opposite directions, approximately 180 degrees from each other. It is the localizing information provided by the coincidence of gamma photons, detected in opposite detectors in the ring of the PET scanner, that helps generate the image.³

The most commonly used radiopharmaceutical in PET imaging is the glucose analogue fluorine-18-deoxyglucose (fluoro-2-deoxyglucose; ¹⁸F-FDG). Just as with glucose, FDG is actively transported into the cell, mediated by glucose

transporters (GLUTs). Once intracellular, FDG is phosphorylated. However, in contrast to glucose, it cannot be dephosphorylated and remains trapped in the cell. This allows sufficient time for imaging before FDG is metabolized. The use of FDG for oncologic imaging relies mainly on increased glucose consumption and overexpression of GLUT proteins in neoplastic cells.

FDG distribution occurs in normal structures such as the brain and the heart and is excreted in the urinary system. There are regions in the body with variable physiologic FDG uptake, such as the digestive and genitourinary tracts.⁴ As a consequence, differentiating physiologic uptake from pathologic uptake may at times prove to be a diagnostic challenge. Increased FDG uptake is not specific to malignancy and can also be seen in various inflammatory or infectious benign pathologic processes as a result of the underlying hypermetabolism.⁵ It is therefore important to be aware of the various pitfalls and physiologic and varying FDG distribution patterns in the body during the interpretation of imaging findings so as not to confuse them with malignancy.

PET not only offers qualitative information but also offers quantification by measurement of radioactivity in a given voxel. SUV (standardized uptake value) is a semiquantitative index of FDG metabolism that is calculated and normalized for injected radiotracer amount and body weight or body surface area. SUV measurements are obtained by placing a region of interest (ROI) or cursor on the area of interest. The values are calculated and displayed by the software of a PET workstation. When repeated PET scans are obtained in the same scanner, with the same acquisition parameters, SUV can serve as a means to assess response to therapy.⁶ Maximum or mean values of SUV can be obtained; however, maximum SUV values are more commonly used in clinical practice because of their reliability and reproducibility compared with mean values.⁶ If FDG were distributed evenly throughout the body, the SUV would be 1.0. Traditionally, an SUV maximum cutoff of 2.5 or greater has been used to differentiate between benign and malignant lesions.⁷ However, the organ in which the measurement is obtained and its comparison to background should be taken into account when determining abnormality of SUV values.

The functional information provided by the PET scan is complementary to the anatomic and morphologic data obtained by the CT scan. PET is limited in regard to accurate anatomic localization of detected abnormal activity, which is especially more of a challenge for abdominal and pelvic imaging. Initial PET scanners provided anatomic registration—that is, superimposition of FDG activity from the PET scan with the corresponding anatomic structure—from CT scans via

separately acquired datasets fused with the aid of software.⁸ This method was easier and more accurate in organs such as the brain, but the same success was not achieved with body imaging, in which bowel peristalsis and motion from breathing caused frequent misregistration artifacts, complicating interpretation. Most of the current PET scans are hybrid units with built-in CT scans in the same hardware, providing immediately sequential acquisition and subsequent coregistration of data without moving the patient. Once the scan is completed, datasets from the PET and CT scans can be reviewed separately or as fused images. The first PET/CT scan became commercially available in 2001 and, since then, PET-only scanners have almost disappeared from the market. Currently, almost all manufacturers offer only hybrid PET/CT scanners.

Attenuation is the loss of the gamma photons emitted from the positron in the patient before they are detected by the scanner. Attenuation is a greater problem with PET imaging because both photons have to travel through the patient for greater distances compared with the traditional single-photon imaging used in nuclear medicine. Only approximately 10% of the photon pairs survive from a given source in the patient.³ As a result, attenuation correction is necessary to obtain high count, good-quality images. Earlier PET scans used external, long-lived radionuclide sources, such as germanium 68 (⁶⁸Ge) or cesium 137, and measured transmission using the same detectors to provide an attenuation map of the patient's body. However, obtaining transmission scans accounted for a significant portion of the scan time in PET-only units, and the length of the scan caused misalignment artifacts.⁹ Current PET/CT scans provide not only anatomic coregistration, but also attenuation correction, which reduces the statistical noise associated with ⁶⁸Ge transmission maps. They also enable a significant scan time reduction, down from 45 to 60 minutes with the PET-alone units to 20 to 30 minutes, thus enhancing patient throughput.

Protocol for Scanning

An agreed-on universal protocol for PET/CT scanning does not yet exist, given that it is still a relatively new and developing modality. Institutions have developed their own modifications to existing protocols to fit their own preferences. There are three main options regarding the CT component while performing a PET scan—to obtain a low-dose CT scan for attenuation correction and image coregistration, a standard-dose CT scan, or a combined standard-dose CT scan with intravenous (IV) and oral contrast. The advantage of the latter options is that they provide diagnostic quality CT scans at the expense of increased radiation dose. Use of a fully diagnostic CT scan using IV contrast is especially important in the evaluation of vascular structures, organ enhancement, and bowel disease, as well as for distinguishing lymphadenopathy and masses from small bowel loops. In our institution, we first obtain a low-dose, noncontrast CT scan followed by the whole-body FDG PET emission scan. Subsequently, a diagnostic quality transmission CT scan is obtained using IV and oral contrast agents, which maximizes diagnostic information and minimizes the risk of artifacts.

In CT imaging, contrast agents are administered to enhance tissue contrast and differentiation and improve lesion localization and characterization. However, protocol modifications are necessary to avoid artifacts and ensure accurate attenuation correction on PET scans.¹⁰⁻¹² Attenuation can be overestimated in PET in the presence of positive contrast agents.¹³⁻¹⁶ The

resulting overestimation of attenuation may lead to potential artifacts, with images demonstrating increased FDG uptake in areas of high contrast concentration. IV contrast causes artifacts that are mainly limited to venous vessels close to the injected bolus, whereas positive oral contrast agents may cause an overestimation of FDG uptake up to 20%; this may be even more problematic when the patient has poor peristalsis or an obstruction causing accumulation of contrast in the bowel.¹⁴ The same applies to metallic implants in the body, which frequently causes attenuation correction artifacts. Non-attenuation-corrected images and the CT scan can serve as problem-solving tools in these cases, because artifacts will be found only on the attenuation-corrected data.

Although much of the misregistration caused by bowel peristalsis and patient motion has been alleviated by the use of CT, respiratory misregistration represents a persistent problem in precluding optimal image fusion. The PET scan is acquired over approximately 30 minutes during shallow respiration, whereas the attenuation-corrected CT datasets are acquired in seconds, during which the patient is instructed to breathe quietly or perform a breath-hold maneuver. The ideal breathing protocol remains to be determined. Several investigators have suggested that optimal fusion occurs with limited expiratory breath holding,^{17,18} whereas others have suggested fusion images of equal quality with shallow breathing.¹⁹

Patient Preparation and Scanning

Our institutional protocol will be discussed here. Our patients are asked to fast for a minimum of 6 hours prior to PET/CT to optimize FDG uptake by tumors and minimize cardiac uptake. Instructions are given to avoid caffeinated beverages. However, water consumption and bladder emptying is encouraged, which aid in the urinary excretion of FDG and minimizes radiation dose to the bladder. FDG is a glucose analogue with a similar metabolism, as discussed earlier. Its uptake is affected by insulin and glucose levels in the blood. Hyperglycemia competes with and decreases FDG uptake by tumors; therefore, before the injection, a blood sugar measurement is obtained. The desired glucose level is below 200 mg/dL and the optimal level is below 150 mg/dL. Diabetic patients are instructed to avoid insulin injection within the 4 hours prior to the scan. In cases of higher glucose levels, measurement is repeated subsequent to light exercise, or sometimes even an injection of insulin is administered after an endocrine consultation.

After the IV injection of FDG (140 μ Ci/kg), patients are kept in a darkened room and encouraged to avoid excessive physical activity, as well as chewing and talking, until the time of the scan. Neutral oral contrast is given at the same time of injection for the subsequent diagnostic CT scan. We typically use two to three bottles (450 mL) of VoLumen (E-Z-EM, Lake Success, NY) for our neutral attenuation oral contrast agent. This is a low-density barium sulfate suspension that distends the bowel without increasing intraluminal attenuation. One hour after the administration of FDG, a static and emission PET scan is obtained. A transmission nonattenuation CT scan is obtained at the same time for attenuation correction at 120 kVp and 60 mAs during quiet breathing, with a slice thickness of 5 mm and overlap of 1.5 mm. A fully diagnostic helical CT scan using IV contrast is obtained subsequent to the emission PET scan during quiet breathing at approximately 140 kVp and 200 mAs, with a slice thickness and overlap of 5 mm.

Esophagus

Esophageal cancer is a leading cause of worldwide cancer mortality. The American Cancer Society (ACS) estimated 17,990 new diagnoses and 15,210 deaths from esophageal cancer in 2013. The lifetime risk of esophageal cancer in the United States is about 1 in 125 in men and about 1 in 435 in women.²⁰ Complete resection of the tumor is the only potentially curative treatment in patients who do not have distant metastases or locally advanced disease. Depending on the stage of the disease, various treatment options exist, ranging from endoscopic resection to primary surgical esophagectomy to chemotherapy and radiotherapy. These treatment modalities lead to substantial morbidity and mortality, which makes accurate staging and pretreatment planning crucial. PET is widely used in clinical practice in the management of patients with esophageal cancer. In the United States, the Centers for Medicare & Medicaid Services (CMS) have approved the use of PET and PET/CT in the diagnosis, staging, and restaging of esophageal cancer.

In the proximal and midesophagus, squamous cell carcinoma predominates, whereas adenocarcinoma is mostly seen in the distal esophagus and esophagogastric junction. In recent years, there has been a dramatic increase in the incidence of adenocarcinoma of the esophagus, but the incidence of squamous carcinoma has remained relatively stable. Whether squamous or adenocarcinoma, PET scanning does not indicate a distinct difference between the two as a diagnostic tool.²¹ The most significant risk factor for adenocarcinoma is gastroesophageal reflux disease, whereas alcohol consumption and smoking are the two major risk factors for squamous cell carcinoma.

PET has limited value as a screening modality and problem-solving tool in disease exclusion prompted by abnormal findings in other diagnostic modalities because of its low specificity.³ A variety of physiologic or benign entities can cause uptake of FDG in the esophagus.^{22,23} Low-intensity, linear physiologic uptake has been described and is thought to represent swallowed secretions or smooth muscle activity. In cases of reflux esophagitis, mild to moderate intensity linear uptake can be seen predominantly in the distal esophagus.²⁴ Radiation esophagitis can also lead to uptake of varying intensity, limited to the zone of radiation.²⁵ Barrett's esophagus, a precursor to adenocarcinoma, is columnar metaplasia of the distal esophagus. It is a complication of reflux esophagitis and has been associated with more intense uptake in the distal third of the esophagus. Other pitfalls include uptake in paraesophageal brown fat, atherosclerotic plaque in the adjacent aorta, and asymmetric uptake in the vocal cords.^{26,27} Recognizing these patterns because they are commonly seen pitfalls and correlating PET findings with the CT images to avoid misdiagnoses are important. However, when uptake is distinctly focal and intense, especially when a corresponding focal mass is seen on the CT scan, diagnosis is highly suspicious for esophageal cancer. In patients for whom the diagnosis is unknown or the PET scan is obtained for other reasons, it is reasonable to recommend endoscopic correlation.

STAGING

Accurate disease staging is critical in choosing the appropriate treatment option and determining the prognosis of esophageal cancer. PET/CT has been widely used for staging of esophageal cancer, especially for the detection of distant metastasis and to

determine whether patients are candidates for surgery. The clinical staging of esophageal cancer is assessed with the TNM staging system developed by the American Joint Committee on Cancer (AJCC) staging guidelines. The depth of tumor invasion through the layers of the esophagus determines the T (tumor) status of the disease, and the N (node) status of disease is determined by the presence (N1) or absence (N0) of regional lymph node metastasis. Detection of distant metastasis (M) determines the M status (M1 or M0) of disease.²⁸ Lymph node metastasis to the cervical lymph nodes in upper esophageal cancer and to the celiac axis lymph nodes in lower esophageal cancer is designated as an M1a status. All other distant lymph node metastases fall into the M1b category. This categorization has prognostic value because patients with M1a disease have a worse prognosis compared with those with N1 disease.²⁹

Detection rates of PET for primary tumor is greater compared with CT, ranging from 83% to 96% in various studies.³⁰⁻³² Patients with T1 (invasion of the lamina propria or submucosa) or T2 (invasion of the muscularis propria) disease primarily undergo surgical resection for curative treatment, whereas patients with T3 (invasion of the adventitia) or T4 (invasion of adjacent structures) disease usually require neoadjuvant chemotherapy or combined chemotherapy and radiation therapy. Although PET has a higher sensitivity in the detection rate of a primary tumor compared with CT, it is of limited value in T staging because it provides no data about the depth of invasion.^{30,33} PET is also limited in spatial resolution; thus, false-negative results occur in small tumors and in tumors that are well differentiated.³⁴ In a study evaluating the usefulness of PET in superficial esophageal cancers, Little and colleagues found that PET was able to detect only 45% of in situ lesions (Tis) and 69% of T1 lesions and was unable to differentiate between the two.³⁵ Endoscopic ultrasound (EUS), however, can accurately determine the T stage.³⁶ In one meta-analysis, which included 49 studies and 2558 patients, the pooled sensitivity and specificity of EUS for diagnosing the T stage were 81.6% and 99.4% in T1, 81.4% and 96.3% in T2, 91.4% and 94.4% in T3, and 92.4% and 97.4% in T4 disease, respectively.³⁷

Various studies have not shown a substantial added benefit of PET for the detection of regional lymph nodes, for which EUS is the standard diagnostic tool. In a prospective study conducted by Flamen and associates, PET had a sensitivity of only 33% in the detection of regional lymph node metastases compared with 81% for endoscopic ultrasound.³⁰ In the meta-analysis by Puli and co-workers, the sensitivity of EUS for diagnosing the N stage was 84.7%, which improved to 96.7% with the use of fine-needle aspiration (FNA).³⁷ In another prospective study of 42 patients, Lerut and colleagues found that PET had a lower accuracy for the diagnosis of locoregional nodes compared with combined CT and EUS (48% vs. 69%), with a significantly lower sensitivity (22% vs. 83%).³⁸ According to a meta-analysis of 12 studies conducted by van Westreenen and associates, the pooled sensitivity and specificity of PET for the detection of locoregional lymph node metastases were 51% and 84%, respectively.³⁹ Unlike other tumors, locoregional lymph node metastases of esophageal cancer are in close proximity to the primary tumor. It is believed that intense FDG uptake of the primary tumor can obscure the uptake of these immediately adjacent lymph nodes, thus creating difficulty in the differentiation of a primary tumor from locoregional lymph node metastasis.

The additional value of PET in the evaluation of nodal status may lie in its high specificity. In the study by Flamen

and co-workers,³⁰ the specificity of PET was 89% compared with 67% with EUS. In another prospective study by Kato and colleagues, PET had an incremental value over CT in the initial staging of esophageal carcinoma in 14% of patients by accurately showing nodal metastasis in six patients with no positive CT findings and absence of disease in six other patients with positive CT findings.⁴⁰ With PET/CT, anatomic and morphologic data obtained from CT are combined with functional information obtained from PET, thus improving detection rates of metastases. In esophageal cancer, metastatic involvement can be seen by histologic analysis in small lymph nodes and, conversely, benign causes of lymph node enlargement are commonly seen in the mediastinum. A morphologically abnormal or enlarged lymph node may show no FDG uptake; conversely, a small, normal-appearing lymph node may demonstrate FDG uptake. In this sense, PET and CT are supplemental to one another. When PET/CT is compared with PET in the assessment of locoregional lymph node metastasis, Yuan and colleagues showed an improved sensitivity of 94%, accuracy of 92%, and negative predictive value of 92% with PET/CT compared with 82%, 87%, and 86%, respectively, with PET only.⁴¹

The current sensitivity rates in detection of locoregional lymph nodes with PET deem its use for the classification of the N stage of disease not sufficient for accurate presurgical planning. A multimodality, multidisciplinary approach using PET, CT, and EUS should be followed for accurate staging of nodal status in patients with esophageal cancer.

The primary role of PET in the management of esophageal cancer is in its value for detecting distant lymph node or solid organ metastasis⁴² (Fig. 7-1). Although patients with M1a disease may benefit from neoadjuvant chemoradiation, radical surgery is contraindicated in patients with M1b disease. Patients with M1b disease are only offered palliative treatments and systemic chemotherapy.⁴³ PET is very useful for the detection of common sites of distant nodal metastases, such as cervical lymph node metastases in upper esophageal cancer and celiac axis lymph node metastases in lower esophageal cancer.^{38,44} In the study by Lerut and associates, the accuracy and specificity of FDG-PET for distant nodal metastasis (M1a) was significantly higher compared with the combined use of CT and EUS (86% vs. 62% and 90% vs. 69%, respectively). In the same study, FDG-PET scanning correctly upstaged 12% of the patients.³⁸

The most common solid organ metastasis of esophageal cancer is to the liver and lungs, followed by bone.⁴⁵ Metastatic disease is present in 20% to 30% of patients with esophageal cancer at initial presentation.⁴⁶ PET has shown to be more accurate and sensitive for the assessment of distant disease compared with CT and EUS.^{38,46-49} The meta-analysis conducted by van Westreenen and co-workers demonstrated a pooled sensitivity and specificity of 67% and 97%, respectively, for detection of distant metastases by PET.³⁹ PET/CT has been shown to prevent surgery by upstaging disease via identifying distant metastases not seen by CT in approximately 14% (5 of 36) of patients in a study by Flanagan and colleagues⁴⁶ and in 28% (7 of 25) of patients in another study by Rankin and associates.⁵⁰ Heeren and co-workers found that PET upstaged 15 patients (15 of 74; 20%) correctly as M1 disease, missed by CT and EUS, and correctly downstaged 4 patients (5%) from M1 to M0 disease, with an overall incremental value of 25%.⁵¹

Figure 7-1 Midesophageal cancer. **A.** Sagittal contrast-enhanced CT scan demonstrates focal circumferential thickening of the midesophagus (solid arrow) suspicious for malignancy. A large, suspicious, low-density gastrohepatic lymph node (dashed arrow) is also seen. **B.** Corresponding sagittal fused PET/CT image shows intense FDG uptake in the midesophagus (solid arrow) and in a gastrohepatic lymph node (dashed arrow).

RESTAGING AND TREATMENT RESPONSE

The accuracy of CT for the detection of recurrent disease or evaluation of treatment response is limited because of the difficulty of differentiating post-treatment changes of inflammation and fibrosis from viable tumor. Morphologic changes do not always reflect tumor response because tumor size may remain stable, despite the viable tumor cells. Guo and colleagues⁵² evaluated PET/CT for disease recurrence and divided anatomic sites of recurrence to local, regional, and distant. The study demonstrated sensitivity values of 96.9%, 85.9%, and 90.5% and specificity values of 50%, 92.2%, and 89.9%, respectively. PET/CT was of low specificity for the evaluation of local recurrence. In the perianastomotic region, EUS is much more sensitive and specific for the detection of recurrence⁵³; however, in the post-treatment patient, the use of endoscopy may be limited because of scarring, inflammation, postradiation esophagitis, or luminal stenosis in the anastomotic region. Therefore, just as with initial staging, a multimodality approach should be applied for restaging esophageal cancer following treatment.

In a meta-analysis by Westterterp and associates⁵⁴ comparing the accuracy of CT, EUS, and PET in the assessment of response to neoadjuvant treatment, the maximum joint sensitivity and specificity values for CT, PET, and EUS were 54%, 85%, and 86%, respectively. PET and EUS had equivalent accuracy, but

the invasive nature and limitations of EUS in the post-treated esophagus were noted. EUS was not feasible in 6% and suboptimal in 14% of patients.

Another study conducted by Cerfolio and co-workers⁵⁵ investigated the accuracy of PET/CT, EUS with FNA, and CT for restaging following neoadjuvant chemotherapy and found that PET/CT accurately predicted complete response in 89% of patients compared with 67% with EUS-FNA and 71% with CT. The accuracy for detecting nodal disease was also superior with PET/CT, 93%, compared with 78% each with EUS-FNA and CT.

Response rates to neoadjuvant treatment are variable with esophageal cancer. Favorable response rates have ranged from 16% to 31% of patients in several published series.⁵⁶⁻⁵⁹ Patients who do not respond to neoadjuvant treatment may have a worse prognosis because of adverse effects of treatment or delay in surgery. Therefore it is crucial to have a test to select the pool of responders accurately and individualize treatment accordingly. PET has been widely used for this purpose.

Many studies have shown a strong correlation of FDG uptake with pathologic stage and survival in esophageal cancer.⁶⁰⁻⁶⁵ This has led to various studies investigating the use of the standardized uptake value (SUV) in determining the metabolic response to neoadjuvant treatment.

Ott and colleagues divided patients based on a predetermined rate of SUV reduction before and after neoadjuvant chemotherapy and classified them into metabolic responders and nonresponders in a prospective study of 65 patients. They found that metabolic response significantly correlated with pathologic response and median survival.⁶⁶

The Municon trial was a prospective study by Lordick and associates, which included 119 patients undergoing neoadjuvant chemotherapy, using PET to assess metabolic response rates in guiding treatment of distal esophageal adenocarcinoma.⁶⁷ On the basis of a cut-off of 35% reduction in the maximum SUV (SUV max), patients were divided into metabolic responders and nonresponders following neoadjuvant chemotherapy. A major histologic response was seen in 58% of metabolic responders compared with 0% in nonresponders. Event-free and overall survival rates were also significantly better in the responder group at 29.7 versus 14.1 months in nonresponders. This study confirmed the benefit of PET in the metabolic evaluation of treatment response in patients receiving neoadjuvant chemotherapy and the feasibility of PET-guided treatment algorithms.

For years, the World Health Organization (WHO) criteria and Response Evaluation Criteria in Solid Tumors (RECIST) have been used to follow treatment response in solid tumors, which used anatomic metrics based on tumor size reduction.^{68,69} However, it is known that metabolic response usually precedes and is more accurate than morphologic response.⁷⁰ With the introduction of molecularly targeted treatment options and the use of PET to assess the metabolic treatment response, these conventional evaluation methods have become of limited value. Recently, Wahl and co-workers introduced the PET Response Criteria in Solid Tumors (PERCIST), which is a new quantitative assessment of the metabolic response of tumors.⁷¹ Yanagawa and colleagues compared the use of RECIST to PERCIST and found that PERCIST was the strongest independent predictor of outcomes in patients receiving neoadjuvant chemotherapy for esophageal cancer.⁷²

PET/CT has also been used for radiation treatment planning. Calculating gross tumor volume in radiation therapy for the

accurate delineation of tumor margins to achieve the best conformity index, the ratio between target tumor volume and irradiated volume, is necessary to treat the tumor successfully while keeping treatment-related complications to a minimum. The use of PET leads to improved accuracy of tumor volume calculation, with up to 20% changes in the calculated tumor volume compared with CT.^{73,74} In a study by Leong and associates, the use of CT only compared with PET caused a geographic miss of gross tumor volume, predominantly in the longitudinal direction, in 31% of patients.⁷⁵ However, it is a developing method, and interobserver variability exists. More studies are needed before the use of PET/CT for radiotherapy planning gains widespread clinical use.

CONCLUSION

The main value of PET for the staging of esophageal cancer is its ability to detect distant lymph node and organ metastases otherwise not detected with other diagnostic modalities, thus altering the treatment in patients with more advanced disease status. Staging attempts should not be limited to PET because of its inherent limitations in T and N staging of disease. Ideal staging would use PET/CT for the detection of distant metastasis with precise anatomic localization and morphologic characterization provided by CT, supplemented by EUS for the improved detection of locoregional lymph nodes and assessment of depth of tumor invasion.

Another major strength of PET is its ability to evaluate treatment response more accurately by determining temporal changes in metabolic activity, thus providing the opportunity to identify those who do not respond to treatment and make alterations in their management. Standardization of scan timing, specific imaging protocols, and the establishment of PET treatment guidelines have yet to be determined. Further studies are needed to establish such standards.

Stomach

Gastric cancer is one of the most common primary gastrointestinal (GI) tract malignancies worldwide. It is often asymptomatic or causes nonspecific symptoms in its early stages. By the time symptoms occur, the cancer is often advanced and commonly metastatic, which accounts for its overall poor prognosis. As a result, gastric carcinoma, especially prevalent in Asian countries, is the second leading cause of cancer mortality, accounting for 600,000 deaths annually worldwide.⁷⁶ Cure can only be achieved by gastric and adequate regional lymph node resection.^{77,78} However, the prognosis remains poor and recurrence rates are high, despite surgical resection and neoadjuvant therapy. As with other cancers, accurate preoperative staging is crucial in determining the most appropriate treatment option and whether curative surgery should be attempted. The main use of PET in gastric cancer is primarily for the detection of distant metastases. It has limited use in the primary diagnosis and detection of lymph node status.

When interpreting PET images for gastric carcinoma or for incidental findings in studies performed for other causes, it is helpful to keep several pitfalls in mind to avoid misdiagnoses. Several benign inflammatory or infectious causes, such as gastritis secondary to medications or *Helicobacter pylori* infection, may frequently cause nonspecific, diffuse FDG uptake of the stomach. This may challenge interpretation because this pattern

of FDG uptake can also be seen in infiltrative primary or metastatic adenocarcinoma and lymphoma.⁷⁹⁻⁸¹ Physiologic uptake in a nondistended stomach with collapsed gastric folds may also accentuate background uptake; the use of water ingestion or low-density oral contrast to distend the stomach adequately before PET scanning is recommended by many to increase the accuracy of PET.⁸² In these cases, clinical correlation for the patient's symptoms of gastritis, recent endoscopy, or underlying primary malignancy may be helpful. In patients with unexplained diffuse or focal, moderate- to high-intensity uptake, correlation with endoscopy should be recommended.²³

Gastric cancer is staged by the standard TNM classification according to the depth of tumor invasion through the gastric wall (T), status and number of lymph nodes (N), and presence of metastasis (M).⁸³ Gastric cancer usually occurs at the gastroesophageal junction; the most common histologic type is adenocarcinoma (>90%) followed by less common types such as mucosa-associated lymphoid tissue (MALT) lymphoma, carcinoid tumor, and sarcomas. Currently, no routine screening programs exist in the United States for the prevention or detection of gastric cancer. Prompted by suspected clinical or imaging findings, the diagnosis is usually made with endoscopy, along with tissue sampling.

CT is the most commonly used modality for more locally advanced disease to stage and assess the extent of the primary tumor, to evaluate for spread to locoregional lymph nodes, and at the same time to determine metastatic status.⁸⁴ CT provides a rapid overall assessment of local and distant disease based on morphologic changes and tissue enhancement patterns. However, the use of CT, as for other cancers, is limited in the detection of nonenlarged local lymph nodes that may harbor tumor cells and has limited specificity because of benign entities that may cause lymph node enlargement. CT may also be limited for the detection of peritoneal and hematogenous metastases.^{85,86} Unfortunately, approximately 23% of patients who are otherwise not suspected to have metastases with conventional imaging modalities are found to have metastatic disease during surgery, precluding curative intent.⁸⁷ This has led several investigators to evaluate the value of PET/CT for detecting local and distant disease preoperatively.

In early gastric cancer, EUS can accurately T-stage mucosal and submucosal lesions, which are generally considered endoscopically resectable if limited to the gastric wall.⁸⁸ According to a study by Xi and co-workers, the overall accuracy of EUS for determination of the T stage was 80.0% and for T1, T2, T3, and T4 was 100%, 71.4%, 87.5% and 72.7%, respectively.⁸⁹ EUS is more accurate for assessing the depth of wall invasion in early cancer compared with other imaging modalities, including CT, but is limited in the assessment of locally advanced disease and the detection of distant metastases.⁹⁰ In a recent meta-analysis by Dassen and colleagues, the sensitivity of PET for the detection of the primary tumor ranged from 26% to 63% for early-stage gastric cancer and from 93% to 98% for locally advanced gastric cancer.⁹¹ Early-stage tumors are not detected at an equal sensitivity compared with more advanced tumors,^{92,93} which could be related to the difficulty in detecting focal uptake in a background of diffuse physiologic uptake or to the limited resolution of PET/CT.⁹⁴ Certain types of gastric cancers, such as MALT lymphoma (MALToma), mucinous carcinoma, and signet ring cell carcinoma, are also known to have low levels of FDG uptake, with limited sensitivity values.⁹⁵⁻⁹⁸ PET should not be used in the work-up of these patients. Kim and associates

have shown that signet ring cell gastric carcinoma has the lowest sensitivity for the detection on PET, 15%, whereas other types of gastric cancer have moderate sensitivity levels ranging from 30% to 71%.⁹⁹ According to a study by Stahl and co-workers, the sensitivity of PET also differs according to the histologic type of cancer, as described by the Lauren system, with a detection rate of 83% for the intestinal type versus 41% for the diffuse type.⁹⁵ Therefore it can be concluded that PET is of limited value in the detection and T staging of gastric cancer.

In a study by Chen and colleagues assessing the usefulness of PET for the preoperative staging of gastric carcinoma, the amount of FDG uptake correlated with macroscopic type, tumor size, lymph node metastasis, histologic type, and TNM stage of the tumor.¹⁰⁰ PET had an accuracy similar to that of CT for diagnosing local and distant lymph node metastases as well as peritoneal status; however, in assessing local lymph node status, PET had a higher specificity than CT (92% vs. 62%). Moreover, PET provided additional diagnostic value in 10 of 68 (15%) of patients by upstaging 4 (6%) and downstaging 6 (9%) patients. In a study by Namikawa and associates, the sensitivity, specificity, and accuracy of PET/CT in assessing regional lymph node metastasis were 64.5%, 85.7%, and 71.1%, respectively.⁹⁴ In another prospective study by Kim and co-workers, which included 73 patients with gastric cancer, the sensitivity, specificity, positive predictive value, and negative predictive value of PET for detecting lymph node metastases were 40%, 95%, 91%, and 56% respectively.⁹⁹ Currently, PET is considered to have low sensitivity and accuracy but high specificity for the detection of lymph node metastases. This is in part related to the low spatial resolution of PET and the difficulty in distinguishing uptake of the primary tumor or background physiologic uptake from the adjacent small perigastric lymph nodes, as discussed earlier for esophageal cancer. The benefit of PET over CT could be in its high specificity and positive predictive values for the assessment of locoregional lymph nodes as well as a theoretic increased accuracy for the detection of distant lymph node metastases (e.g., those in the retroperitoneum). To date, there have not been many studies comparing PET/CT to CT or PET alone for the evaluation of locoregional lymph nodes in gastric cancer. The added benefit of hybrid imaging with PET/CT has been well demonstrated in the preoperative evaluation of esophageal cancer and may have a role and added benefit for gastric cancer.⁴¹

Gastric cancer usually metastasizes to the liver, lungs, adrenal glands, and ovaries.¹⁰¹ The major advantage of PET is in the detection of these distant solid organ metastases, which may be metabolically active much sooner than they become morphologically apparent on CT. In one series, the overall sensitivity and specificity of PET to detect distant metastases was found to be 71% and 74%, respectively, with high values for liver and lung metastases but lower values for malignant ascites and malignant pleural effusion.¹⁰² Both CT and PET have limited sensitivity in the detection of peritoneal carcinomatosis, which is frequently diagnosed intraoperatively.^{103,104} Diffuse peritoneal FDG uptake or uptake in gross tumor deposits of omental caking can be seen; however, diffuse, small, nodular peritoneal deposits usually fall below the resolution of PET, although they can sometimes be detected by CT. Despite the added benefit of detecting distant unsuspected metastases in some cases with a high specificity,¹⁰⁵ the added value of PET/CT in the diagnosis and work-up of patients with gastric cancer has yet to be determined.

PET/CT is useful in the detection of recurrence subsequent to surgical resection and in the assessment of treatment response to preoperative chemotherapy. PET can frequently differentiate treatment-related morphologic changes seen on CT from tumor recurrence. In a recent meta-analysis, Zou and Zhao analyzed results from 8 studies, which included a total of 500 patients, and found that the pooled sensitivity and specificity of PET/CT for the detection of local gastric cancer recurrence following surgery were 86% and 88%, respectively.¹⁰⁶ Neoadjuvant therapy is frequently being used in the treatment of gastric cancer to improve survival with the subsequent surgical resection. Treatment response by CT is assessed with changes in tumor size following the RECIST criteria,⁶⁹ which may sometimes be sub-optimal. In some cases, the tumor may not reduce in size, despite no longer harboring tumor cells. PET can detect and separate treatment responders at an earlier phase than CT, thus reducing treatment-related morbidity and preventing delays in surgical treatment.⁸⁷ In this regard, PET also provides prognostic information, because patients who do not respond to chemotherapy usually have more aggressive tumor biology.

There has been increasing interest recently in a new radiotracer, ¹⁸F-fluorothymidine (FLT), in PET for the evaluation of gastric cancer, with the aim of acquiring more accurate diagnostic and staging information.¹⁰⁷ Herrmann and associates have compared the feasibility of FLT-PET to FDG-PET and found FLT-PET to have a sensitivity of 100% in primary tumor

detection compared with 69% with FDG-PET.¹⁰⁸ These modalities are relatively new and warrant further investigation to gain acceptance in clinical practice.

To conclude, although PET may not have a role in the detection of the primary tumor and regional lymph nodes, it may provide valuable information with regard to increased specificity of findings, detection of distant metastases, and evaluation of treatment response. Fused PET/CT has been of additional value for various cancers, but its role in gastric cancer has yet to be fully determined. Initial results of studies investigating some new PET radiotracers appear promising.

Small Bowel

The most common small bowel cancer is adenocarcinoma which is mostly seen in the duodenum, followed by the jejunum, with the exception of patients with Crohn's disease, in whom the most common location is the ileum.^{109,110} Metastases to the small bowel can also occur, usually seen with malignant melanoma, followed by breast and lung cancers.^{111,112} Less commonly seen tumors of the small bowel include neuroendocrine tumors (NETs), gastrointestinal stromal tumors (GISTs), and sarcomas (Fig. 7-2). Some form of surgical treatment is offered with curative intent during early-stage cancer and for palliation, primarily to prevent obstruction in the more advanced stages. Neoadjuvant therapy is frequently used in

Figure 7-2 Duodenal neuroendocrine tumor. **A.** Axial contrast-enhanced CT scan shows a round mass at the junction of the descending and transverse duodenum (arrow). **B, C.** Corresponding axial fused PET/CT scan (**B**) and whole-body coronal maximum intensity projection (MIP) PET scan (**C**) demonstrate focal, intense FDG uptake in the mass (arrow). Also note the diffuse heterogeneous low-level uptake of the small bowel in the background.

more locally advanced disease, along with subsequent surgical resection, whereas systemic chemotherapy, which appears to provide a modest survival benefit, is offered to patients with more widespread disease.¹¹³ Given the variety of surgical and medical treatment options, accurate staging is crucial in deciding the optimal treatment to provide the most survival benefit to patients while minimizing unnecessary, treatment-related morbidity. Given the rarity of this type of cancer, the usefulness of PET/CT for the diagnosis and work-up of these patients has not been extensively investigated.

The most common appearance of small bowel carcinoma on PET/CT is focal or segmental wall thickening, with intense FDG uptake.¹¹⁰ However, potential pitfalls in interpretation exist and should be kept in mind to avoid misdiagnoses. The small bowel normally demonstrates diffuse, mildly heterogeneous FDG uptake, which may be more prominent in the pelvis, with multiple bowel loops overlying each other.²³ FDG uptake in the small bowel uptake is nonspecific and can be seen with various infectious and inflammatory causes, including Crohn's disease¹¹⁴ (Fig. 7-3). Primary and metastatic small bowel malignancies, GISTs, and lymphomatous involvement of the small bowel can also show FDG uptake. Interpretation of the PET scans should be made in conjunction with CT findings to localize and characterize focal unexpected FDG uptake accurately, because a variety of bowel wall-thickening patterns have been well described in the CT literature.^{115,116}

In patients suspected to have advanced disease, PET/CT would have the potential added benefit of staging the disease by identifying locoregional lymph node and distant metastases, evaluating treatment response, and restaging the disease

subsequent to treatment. PET/CT has been used successfully in the imaging of small bowel tumors, as reported in various studies.¹¹⁷⁻¹²⁰ PET/CT permits the detection and characterization of local and distant lymph node involvement and identification of unsuspected distant metastases, including the liver. Its added benefit has been proven in the work-up of patients with other GI tract malignancies, including esophageal, colorectal, and gastric cancers (see earlier). Currently, however, PET-CT's accuracy and added benefit for detecting local and distant metastatic disease from small bowel adenocarcinoma have not yet been studied sufficiently to allow for their accurate determination.

GISTs are nonepithelial neoplasms typically arising in the bowel wall, mesentery, or omentum. Most GISTs occur in the stomach, followed by the small bowel, accounting for approximately 10% to 15% of small bowel cancers. All GISTs have malignant potential, with a worse prognosis in those that are of nongastric origin, large in size, and with a high mitotic index.¹²¹ PET has been used for detecting the malignant potential of GISTs by the use of FDG uptake and for assessing metastatic disease before surgery for accurate staging.¹²²⁻¹²⁴ However, its full potential for the work-up of patients with GISTs, as well as the indications and the selection of patients for which PET/CT would be useful, are yet to be determined.

NETs are typically not FDG-avid, so novel PET radiotracers such as ⁶⁸gallium-DOTATATE, ⁶⁸gallium-DOTA-NOC, and ¹⁸F-L-DOPA are being developed for applications in NET evaluation and have shown highly promising results. In a study by Haug and co-workers, ⁶⁸gallium-DOTATATE PET/CT identified NET in 29 of 36 patients and excluded the presence of a NET in 61 of 68 non-NET patients in a pool of 104 patients suspected to have NET.¹²⁵ They reported a sensitivity of 81% and specificity of 90%. PET/CT had false-positive and false-negative results in 7 patients, with each indicating positive and negative predictive values of 81% and 90%, respectively, and an accuracy of 87%.^{125,126}

The use of PET/CT for the evaluation of small bowel tumors has yet to be determined, given the lack of sufficient data, which are restricted by the rarity of this type of cancer. Based on our experience, as well as extensive data obtained for other GISTs, PET/CT could be used as an adjunctive modality in the work-up of patients with small bowel tumors to detect local and advanced stages of the disease.

Colon and Rectum

Colorectal cancer is the third most common cancer in men and women and the second leading cause of cancer mortality in the United States. The National Cancer Institute estimated that approximately 142,000 new diagnoses would be made and 50,000 patients would die from colorectal cancer in 2013.¹²⁷ Surgery is the most common and only potentially curative treatment option for patients who do not have widespread distant metastases. Almost all patients with colon cancer undergo some form of surgery, whether an attempt for palliation or cure. Surgical resection of limited metastatic disease to the liver is also frequently performed. Patients with early-stage rectal cancer undergo local excision and/or radiation therapy, whereas for those with locally advanced disease, neoadjuvant chemoradiation followed by surgery is frequently used.

Although CMS has approved the use of PET and PET/CT in the diagnosis, staging, and restaging of colorectal cancer, the

Figure 7-3 Crohn's disease. **A.** Coronal contrast-enhanced CT scan demonstrates bowel wall thickening and increased enhancement in the terminal ileum (solid arrows) and in the distal small bowel loops (dashed arrow). **B.** Corresponding whole-body MIP PET scan shows intense FDG uptake in the affected bowel loops (arrows).

main role of PET in the management of colorectal cancer is in the evaluation of locoregional lymph node and distant metastases. PET has limited value in the initial diagnosis and screening of colorectal cancer. In a study by Chen and colleagues investigating the use of PET as a screening tool in 3210 asymptomatic individuals, only 14 advanced adenoma (>1 cm) and 6 cancer diagnoses were made.¹²⁸ At present, radiation and cost considerations, as well as low positive predictive values, prohibit PET from gaining widespread acceptance as a screening tool.

FDG uptake in the colon is heterogeneous, and diffuse low intensity uptake is common. Focal, moderately intense physiologic uptake can also be seen, especially surrounding the ileocecal valve and in the right colon secondary to a high concentration of lymphoid tissue in this region.¹²⁹ Despite the high sensitivity of PET for the detection of primary tumors (95% to 100%), its specificity is limited because of a high number of benign pathologies that show focal, intense FDG uptake, such as diverticulitis, appendicitis, and abscess formation,^{23,130} which leads to a high number of false-positive studies. However, when there is focal and intense colonic uptake incidentally seen on the PET scan obtained for other indications, correlation with the CT scan is invaluable, because the diagnoses for benign causes of FDG uptake are readily made by CT. Clinical correlation for inflammatory or infectious causes of FDG uptake, such as inflammatory bowel disease or infectious colitis, should be made. In a study by Agress and Cooper, which reviewed the clinical significance of unexpected, abnormal, focal FDG uptake in 1750 patients with PET scans obtained to evaluate known or suspected malignancies, 26 patients with focal colorectal uptake were identified. Among these, 18 were found to be adenomas, 3 were cancers, 2 had benign causes, and 3 were found to be false-positives.¹³¹ Therefore in patients for whom there is no related known diagnosis and CT is unable to explain the uptake, or shows a distinct mass, findings should not be ignored, and endoscopic evaluation should be recommended.

Guidelines for screening of colorectal cancer in average-risk adults were last updated in 2008 in an evidence-based consensus statement that included the U.S. Multisociety Task Force (USMSTF) on Colorectal Cancer (which included the American College of Gastroenterology, American Gastroenterologic Association, and American Society for Gastrointestinal Endoscopy), ACS, and American College of Radiology (ACR). These recommendations were based on tests for cancer detection or tests for cancer and adenomatous polyp detection starting at the age of 50 years.¹³² The former included an annual, guaiac-based, fecal occult blood test, annual fecal immunochemical test, or stool DNA test, all tests with high sensitivity for cancer. The latter group included flexible sigmoidoscopy every 5 years, colonoscopy every 10 years, double-contrast barium enema every 5 years, and CT colonography every 5 years. The guidelines stated that all recommended tests were acceptable options and stressed shared, informed decision making with patients. PET/CT has no role in screening for colorectal cancer for these reasons and was not included in the guidelines.

STAGING

The AJCC recommends the TNM staging system for the clinical staging of colorectal cancer. Because surgery is frequently performed for curative purposes in the early stage of colon cancer, and for palliation or management of complications in the

advanced stage, current staging schemes are based on surgical and pathologic data.³ Although surgical staging is superior because of the evaluation of tumor depth in the bowel wall and microscopic involvement of regional lymph nodes on histopathology, attempts to determine accurate staging during the initial imaging evaluation are important to steer the nature of the surgery, whether it is palliative or curative in intent. The ACR has recommended CT scanning of the chest, abdomen, and pelvis as the initial pretreatment screening study for colon and rectal cancers.¹³³ CT provides speed, convenience, and an overall picture of disease status, permitting identification of complications such as obstruction or perforation from the tumor, which may not be clinically apparent. Accurate local and regional staging is even more important with rectal cancers because it determines the need for administering neoadjuvant chemoradiation. The added benefit of PET/CT in staging is appreciated most with more advanced disease.

The sensitivity of PET for the detection of the primary tumor is up to 100% in patients with a known diagnosis¹³⁴ (Fig. 7-4). A potential weakness of PET in primary tumor detection is that it may have a decreased sensitivity for lesions smaller than 1 cm because of limited spatial resolution and for certain tumor cells such as those of mucinous adenocarcinoma.^{135,136} Despite the strength of PET for the detection of the primary tumor, it does not provide sufficient detail about the depth of tumor penetration through the bowel layers to assess the T stage of disease, which is particularly important for treatment planning in rectal cancer. Patients with transmural disease undergo

Figure 7-4 Rectal cancer. **A.** Sagittal non-contrast-enhanced CT scan shows a midrectal mass (arrow). **B.** Corresponding sagittal fused PET/CT image demonstrates intense FDG uptake in the mass (arrow).

neoadjuvant chemoradiation, whereas those with disease limited to the bowel wall undergo primary surgical resection.¹³⁷ CT cannot discriminate bowel layers either, and its accuracy is limited unless there is gross wall penetration or perirectal invasion by the tumor. A meta-analysis investigating the use of endorectal US, CT, and MRI for the assessment of perirectal invasion has reported a significantly higher sensitivity for US than for CT.¹³⁸ For small rectal tumors, the initial imaging recommendation to assess tumor depth is endorectal US. For large tumors, MRI of the pelvis with contrast is recommended, because endorectal US is very accurate for staging superficial T1 and T2 tumors, but less so for T3 and T4 tumors, which require evaluation of the perirectal fat and mesorectal fascia.^{139,140} All the conventional imaging modalities are limited, however, in the differentiation of peritumoral desmoplastic reaction from actual tumor.¹⁴¹

Because most patients undergo some form of colectomy, the extent of local disease can be histopathologically evaluated by the excision of pericolic and mesenteric lymph nodes. The intensity of uptake in the primary tumor may obscure adjacent small lymph nodes in PET/CT, and it may not detect microscopic involvement; therefore, it has limited value in the preoperative staging of local disease. In a recent meta-analysis by Lu and associates, PET/CT had a pooled sensitivity and specificity of 42.9% and 87.9%, respectively, for the detection of local lymph nodes.¹⁴² Although PET is less sensitive, it was shown to be more specific for the detection of locoregional lymph nodes compared with CT in various studies.^{134,143,144} Given its specificity, PET/CT could be used to improve the detection of finding metastatic lymph nodes that are not in the operative field depicted by other imaging modalities.

The main role of PET/CT in staging colorectal cancer is in the detection of distant metastases (Fig. 7-5). Colorectal cancer most commonly metastasizes to the liver and lungs, followed by

Figure 7-5 Metastatic colon cancer. **A.** Coronal contrast-enhanced CT scan demonstrates multiple, low-density peritoneal implants (arrows) along the surface of the liver in this patient with known mucinous adenocarcinoma of the colon. **B.** Corresponding coronal fused PET/CT shows intense FDG uptake in the peritoneal deposits (arrows). Mucinous tumors have variable and frequently low FDG uptake. However, in this patient, the metastases had intense FDG uptake.

retroperitoneal and iliac lymph nodes, bone, adrenal glands, and soft tissues. Hepatic metastases are most common and are present during initial presentation in approximately 30% of patients. Accurate detection and localization of hepatic metastases are very important, especially if resection of metastatic liver lesions is planned. Some patients may be deemed inoperable, whereas in others more extensive resections may be performed. Currently, contrast-enhanced CT is established as the primary imaging modality to detect and characterize focal liver lesions.¹⁴⁵ MRI is then recommended for further characterization of suspicious or equivocal lesions detected by CT. PET is limited in its ability to detect hepatic metastases smaller than 1 cm,¹⁴⁶ but it is more sensitive and specific compared with CT alone for the detection of hepatic and extrahepatic metastases. Among 43 patients who were evaluated with PET and CT prior to resection of colorectal liver metastases, PET identified additional lesions in 10 patients, which led to cancellation of the surgery in 6 of the patients.¹⁴⁷ In a recent meta-analysis, which included 3391 patients with colorectal cancer metastatic to the liver, the sensitivities of CT, MRI, and FDG-PET were 83.6%, 88.2%, and 94.1%, respectively.¹⁴⁸ When performing a PET/CT, the importance of obtaining a fully diagnostic CT scan, including the portal-venous phase, becomes paramount, especially for the detection of hypoenhancing lesions and potentially non-FDG-avid lesions, commonly seen in cancers of mucinous histology. With recent technologic advances, such as diffusion-weighted imaging and hepatobiliary-specific contrast agents, MRI is becoming increasingly valuable and even more sensitive, especially for the detection of subcentimeter liver metastases. Sahani and co-workers compared PET with MRI using a liver-specific contrast medium, mangafodipir trisodium, for the detection of liver metastases; MRI and FDG-PET had sensitivities of 96.6% and 93.3%, positive predictive values of 100% and 90.3%, and accuracies of 97.1% and 85.3%, respectively.¹⁴⁶ Of the 33 subcentimeter lesions (33 of 79), all were identified by MRI, whereas only 12 were detected by PET.

In a meta-analysis by Wiering and colleagues, the pooled sensitivity and specificity of FDG-PET for detecting hepatic lesions were 88.0% and 96.1%, respectively, and 91.5% and 95.4%, respectively, for extrahepatic disease in colorectal cancer.¹⁴⁹ In contrast with CT, the pooled sensitivity and specificity for hepatic lesions were 82.7% and 84.1%, respectively, and were 60.9% and 91.1%, respectively, for extrahepatic disease. PET resulted in a change of clinical management in 31.6% of patients. PET/CT was found to upstage 14%, downstage 17%, and alter management in approximately 12% of patients with primary rectal carcinoma compared with conventional imaging in a study by Davey and associates.¹⁵⁰ Another study by Gearhart and co-workers investigated the added benefit of PET/CT compared with transrectal US and CT, PET/CT identified discordant findings in 38% of patients, which resulted in a change of treatment plan in 27% of patients.¹⁵¹ These studies clearly indicate that the use of FDG-PET has added value in the diagnostic work-up of patients with colorectal cancer, especially in the evaluation of distant metastases.

RESTAGING AND TREATMENT RESPONSE

For the detection of recurrence in patients treated for colorectal cancer, routine surveillance is mandatory. The American Society of Clinical Oncology (ASCO) recommends annual CT of the chest, abdomen, and pelvis for 3 years, history and physical

examination every 3 to 6 months for the initial 3 years and every 6 months for years 4 and 5, determination of serum carcinoembryonic antigen (CEA) levels every 3 months postoperatively for 3 years, and colonoscopy at 3 years following surgery for surveillance of patients treated for colorectal cancer.¹⁵²

Most common sites of recurrence are locoregional or metastases in the liver. In a retrospective analysis of a total of 2657 patients who had curative resection for colonic cancer, a 5-year cumulative rate of 12.8% and 25.6% was found for local recurrence and distant metastases, respectively.¹⁵³ The most significant risk factor for recurrence was found to be the stage of disease at diagnosis. In a study investigating factors indicating improved survival and recurrence subsequent to resection of colorectal cancer, it was found that young age, general good health, surgery on an elective basis, and early-stage tumor at the time of resection helped improve 10-year survival of patients.¹⁵⁴ Another population-based analysis of 3375 patients with colon cancer found a 5-year cumulative rate of local recurrence of 7.6% in tumors resected for curative intent.¹⁵⁵ Rates of local recurrence are slightly higher with rectal cancer, especially lower rectal cancer, compared with colon cancer. Upper and midrectal cancers are successfully treated with total mesorectal excision, with low recurrence rates, whereas low rectal cancers have higher recurrence rates of up to 10% at 2 years.^{156,157} This is largely because of the scarcity of perirectal fat in the lower rectum, leading to challenges in obtaining an adequate, negative surgical margin during resection.

CT has its limitations in the detection of local recurrence because of distortion of anatomy in the post-treatment bed. Recurrence with extensive inflammatory changes and fibrosis secondary to surgery and radiation therapy may not be morphologically apparent until it is too late. Interpretation of post-treatment changes in the presacral space and pelvis following treatment for rectal cancer is especially challenging. Recurrence in this region reveals itself with very subtle soft tissue changes on CT scans over a long period. In cases of local recurrence, although only 20% of patients can have repeated, complete resection, early discrimination is important because it can enable prompt intervention and may affect patient survival.¹⁵⁸ Because PET is based on metabolic activity, it can better differentiate post-treatment changes from recurrent or residual tumor compared with CT. It is important, however, to keep in mind that in the immediate postsurgical or postradiation treatment period (within the first 3 months), false-positive FDG uptake can be seen.¹⁵⁹ PET has been shown to be more sensitive compared with CT in the presacral region, with a sensitivity and specificity of 100% and 96%, respectively.^{160,161} A recent meta-analysis, which included 510 patients, PET/CT had a pooled sensitivity of 94.1% and specificity of 77.2% in the detection of overall tumor recurrence for colorectal cancer.¹⁶²

In keeping with the ASCO recommendations, serum CEA levels are determined for routine surveillance.¹⁵² CEA levels can detect recurrence with a sensitivity of 59% and specificity of 84%.¹⁶³ CT is commonly used when there is suspected recurrence but has limitations in detecting recurrent metastatic disease when recurrence is in the peritoneum or small lymph nodes or if the tumor is metabolically active but not morphologically apparent. PET/CT can often find sites of disease in patients with abnormal CEA levels but no identifiable metastatic disease on conventional diagnostic work-up. A study by Hung and colleagues, which compared PET, CT, and serum CEA levels for the evaluation of recurrent disease demonstrated

sensitivity and specificity values of 100% and 83% for PET, 33% and 86% for serum CEA level elevation, and 78% and 61% for CT, respectively.¹⁶⁴ A recent study of PET/CT for the detection of recurrent or metastatic disease in patients with a history of colorectal cancer and elevated CEA levels found the sensitivity of PET/CT and CT to be 97.3% and 70.3%, with an equal specificity of 94.4%.¹⁶⁵ In a group of 84 patients, Votruba and associates found that the sensitivity, specificity, and overall accuracy of PET were 80%, 69%, and 75%, respectively, compared with 89%, 92%, and 90%, respectively, for PET/CT for the detection of hepatic and extrahepatic metastatic disease.¹⁶⁶ As with initial staging, distant metastatic disease is identified with a greater sensitivity and accuracy with PET/CT in patients with recurrence from colorectal cancer compared with conventional imaging modalities.

PET/CT is the most sensitive and specific method for detecting overall recurrence, especially at distant sites. Patients with advanced disease are usually treated with a combination of 5-fluorouracil with newer agents, such as irinotecan and oxaliplatin. The 5-year survival with chemotherapy alone is historically less than 1%, although two recent clinical trials using FOLFOX (folinic acid, 5-fluorouracil, and oxaliplatin), FOLFIRI (folinic acid, 5-fluorouracil, oxaliplatin, and irinotecan), or a combination of the two, reported 5-year survival rates of 5% to 10%.^{167,168} Earlier reports suggested that PET/CT is useful in monitoring treatment response to systemic chemotherapy in colorectal cancer and altering treatment when needed.¹⁶⁹ However, several studies have challenged the accuracy of PET/CT in patients who received chemotherapy. In a recent meta-analysis, the pooled sensitivity estimates of MRI, CT, PET, and PET/CT were 85.7%, 69.9%, 54.5%, and 51.7%, respectively, for the detection of colorectal liver metastases in patients treated with neoadjuvant chemotherapy; it was concluded that MRI was the most effective modality for this patient group.¹⁷⁰ Another study showed significantly decreased FDG uptake in colorectal liver metastases in patients treated preoperatively with chemotherapy, resulting in less efficient tumor detection.¹⁷¹ In this report, the explanation given for the decreased accuracy of PET was the significant decrease in hexokinase activity in the metastatic liver tumors following chemotherapy.

Despite advancements in systemic chemotherapy, liver resection is the most effective treatment for achieving long-term survival, offering the possibility of cure in advanced-stage disease confined to the liver.^{172,173} In a study by Selznert and co-workers, PET/CT was superior in establishing the diagnosis of intrahepatic recurrences in patients with hepatectomy, with a specificity of 100% versus 50% for CT.¹⁷⁴

Percutaneous thermal ablation is frequently used in the management of metastatic liver lesions in patients who are not operative candidates because of existing comorbidities. Thermal ablation in these patients has been shown to improve survival.^{175,176} Differentiation between postablation changes and residual disease may at times be challenging with morphologic imaging studies such as CT and MRI. PET can metabolically evaluate the ablation zone in equivocal cases on conventional imaging or in patients in whom additional hepatic or extrahepatic disease is suspected.¹⁷⁷⁻¹⁸⁰ Following ablation, FDG-avid lesions become photopenic, reflecting adequate treatment. Similar to contrast enhancement features of CT, focal areas of increased FDG uptake within the ablation zone suggest residual disease. Inflammatory reactive changes surrounding the

ablation zone usually show uniform, low-level uptake, whereas uptake in residual or recurrent disease is focal, nodular, and intense.¹⁸¹ Lesions that have no enhancement or diffuse peripheral enhancement on CT or MRI often have focal uptake on PET, which could be used to direct subsequent biopsy or repeated thermal ablation.

Numerous liver-directed therapies are available for treating unresectable liver metastases, including radioembolization with yttrium 90 microspheres (Y90) or transarterial chemoembolization. These are second- or third-line treatment algorithms administered to stabilize liver disease, with minimal toxicity, in patients for whom standard systemic chemotherapy regimens have failed. PET/CT has been used to evaluate treatment response to transcatheter arterial chemoembolization and radioembolization with Y90 microspheres.¹⁸² A study by Wong and colleagues showed that a metabolic response after 90Y treatment to one or both hepatic lobes was present in a significantly higher proportion of the lobes assessed by PET compared

with an anatomic response evaluated by CT or MRI.¹⁸³ Further studies are needed evaluating the accuracy and added benefit of PET in patients treated with transarterial, liver-directed therapies.

CT and MRI are more commonly used in current clinical practice for the evaluation of treatment response in the liver. At present, the optimal timing for imaging, cost concerns, and protocols for evaluating treatment response have not yet been established, which prohibit the use of PET/CT as a standard method for evaluating treatment response. However, PET/CT could be used as a problem-solving tool for patients in whom conventional imaging modalities do not provide sufficient information for critical decision making.

In summary, it has been found that PET/CT has the greatest impact for the detection of previously unrecognized sites of hepatic or extrahepatic metastases, detection of local recurrence in the treatment bed, and restaging in patients with suspected local or distant recurrent disease.

Clinical and Angiographic Features

Thrombolytic Therapy for Mesenteric Vascular Occlusion

Bowel Interventions

Reasons for Placement of Needles or Catheters into the Gastrointestinal Tract

Diagnostic Biopsy of Bowel Masses

Enteric Puncture for Diagnostic or Therapeutic Access

Over the past 2 decades, the applications of angiography and interventional radiology in hollow abdominal viscera have dramatically changed.^{1,2} Multidetector computed tomography (MDCT) angiography and magnetic resonance (MR) angiography have replaced much of the diagnostic angiography that had been performed for investigating mesenteric ischemia, diagnosing abdominal masses, and detecting gastrointestinal (GI) tract bleeding sites.³⁻⁷ Interventional applications in the GI tract, however, have dramatically increased. In this chapter, new developments in angiography and interventional radiology of the hollow viscera are addressed.

Preparation of Patients

Certain preprocedural steps can enhance the diagnostic quality of a visceral angiogram. For elective studies, a standard bowel cleansing should be considered to delineate vessels and pathologic findings more clearly. Intravenous (IV) glucagon (1.0 mg) given at the time of the procedure, helps reduce the effects of bowel motion, particularly in studies with digital subtraction.

A Foley catheter is useful for studies of the inferior mesenteric artery because a contrast agent filling the bladder can obscure its branches. It also increases the patient's comfort and helps prevent unnecessary delays during long examinations.

Unless contraindicated, we routinely premedicate patients undergoing visceral angiography with fentanyl (Sublimaze) and midazolam (Versed) in an attempt to achieve the analgesic, anxiolytic, and amnesic effects of these combined agents while maintaining the patient's ability to cooperate. All patients have intraprocedural monitoring of pulse, electrocardiogram, arterial oxygenation (via a pulse oximeter), and blood pressure.

Technical Factors

VASCULAR ACCESS

In general, the femoral arterial route of catheterization is used for abdominal aortography and selective visceral angiography; the safety and ease of this approach are well established. Brachial or axillary access may be used in cases of difficult femoral access or when there is a need to advance a catheter more deeply into a vessel that has a steep caudal course.

CATHETER SELECTION

Our catheter of choice for celiac and superior mesenteric arteriography is a simple angled visceral hook, with a single side hole. For inferior mesenteric arteriography, we prefer a catheter with a short curved tip. For most indications, 5-Fr catheters are used to minimize puncture site complications. An angiographic sheath with a check flow valve is placed to secure vascular access.

Advances in guidewire and catheter technology have made subselective catheterization of visceral vessels easier. These include the development of flexible, hydrophilic, torque control guidewires and catheters that have low coefficients of friction, which allow them to follow wires around complex or tight curves more readily. The addition of microcatheters, microwires in 0.018-inch systems, microcoils, and embolic microspheres has allowed the interventionalist to manage acute GI bleeding, regardless of the source of bleeding.⁸

Figure 8-1 Arterial portography obtained during digital subtraction angiography. Excellent opacification of the mesenteric and portal venous system is achieved after superior mesenteric arterial injection. P, Portal vein; S, superior mesenteric vein.

EQUIPMENT

Digital subtraction angiography (DSA) is the preferred technique for visceral angiography (Fig. 8-1). In addition, digital image processing features greatly facilitate the guidance of complex vascular catheterizations and interventions. The improvement of digital subtraction systems has allowed the performance of angiography with carbon dioxide, providing exquisite angiographic images and minimizing the risk of contrast-induced nephropathy.⁹

Angiography of the Major Visceral Vessels

Visceral angiography begins with injection of the aorta or one of the three major visceral vessels—the celiac artery, superior mesenteric artery (SMA), or inferior mesenteric artery (IMA). Aortic injection is usually limited to situations that pose a risk for selective catheterization, such as suspicion of severe narrowing or occlusion of one or more of the origins of the major visceral vessels, especially in patients with clinical evidence of intestinal ischemia or those with severe aortic atherosclerosis.

The order of examination of the visceral vessels depends on the clinical situation. Thus, in GI bleeding, angiography should begin with the vessel most likely to be bleeding based on clinical history and the results of prior diagnostic studies.

Selective catheterization of the visceral arteries can be performed as an initial step or after aortography. The celiac artery generally arises from the aorta anteriorly, at the middle T12 or upper L1 vertebral level. The SMA originates slightly caudal to the celiac trunk. Generally, 5 to 7 mL/s of contrast medium is injected into these arteries, for a total of 15 to

35 mL; the rate is based on test injections. For the IMA, which usually arises to the left of midline from the abdominal aorta at the lower aspect of the L3 vertebral body, injection at a rate of 3 to 4 mL/s for a total of 12 to 16 mL is generally appropriate. Injection rates are proportionately decreased for the mesenteric branches.

Angiography using carbon dioxide requires a different technique. It is important to remember that carbon dioxide displaces blood and does not mix with it. This causes carbon dioxide images to appear incomplete or “cut.” Most current digital subtraction systems are now equipped with software for carbon dioxide angiography. The use of stacking software is essential to postprocess the original images obtained during carbon dioxide angiography. When performing carbon dioxide angiography, it is essential to use a “closed” carbon dioxide delivery or injection system to minimize the risk of air contamination.¹⁰ The new CO₂mmander system (AngioAdvancements, Fort Myers, FL) is a U.S. Food and Drug Administration (FDA)–registered portable carbon dioxide delivery system. It is composed of a converter, which is connected to a cartridge that holds up to 10,000 mL of medical grade carbon dioxide. The converter is connected to the delivery tubing, which has one-way valves to direct flow in the correct direction. The system safely delivers carbon dioxide at a low pressure and avoids air contamination and explosive delivery. Once the carbon dioxide is loaded in the injection syringe, it is gently injected into the selected artery using an end-hole or multi-perforated catheter. As a general rule, no more than 200 mL of carbon dioxide should be injected within a period of 5 minutes to prevent a vapor lock effect, which is a known complication of excessive carbon dioxide injection into the arterial system.¹¹

Arterial Anatomy of Specific Segments of the Gut

The vascular anatomy of the hollow abdominal viscera is complex. We have used a number of excellent general references in preparing this chapter; the reader is referred to these for more detailed discussions of angiographic and gross anatomy and the embryologic basis for many of the observed anatomic variations.

ESOPHAGUS

From a practical standpoint, only the distal esophageal arterial supply is important for angiographers. The gastroesophageal junction is a reasonably common site of arterial hemorrhage potentially treatable by embolization or vasopressin infusion. This region is typically supplied by branches of the left gastric artery (see later) or the left inferior phrenic artery (Figs. 8-2 and 8-3).

Catheterization of the upper and middle portions of the arteries that supply the esophagus is difficult but, fortunately, rarely necessary. The cervical esophagus typically receives its arterial supply from the inferior thyroid arteries (branches of the subclavian arteries), with predominant supply from the right. Subclavian, common carotid, or aortic branches may also supply this segment. The thoracic esophageal arteries arise directly from the aorta or as branches of the intercostal or bronchial arteries. Esophageal arteries anastomose along the length of the esophagus.

Figure 8-2 Celiac arteriogram. GD, Gastroduodenal artery; H, common hepatic artery; LG, left gastric artery; S, splenic artery; black arrow, branches of the left gastric artery supplying the lower esophagus; white arrow, right gastro-omental artery.

Figure 8-4 Celiac arteriogram. A well-formed gastro-omental anastomosis is present. C, Celiac artery; GD, gastroduodenal artery; H, common hepatic artery; LG, left gastric artery; LGO, left gastro-omental artery; RGO, right gastro-omental artery; S, splenic artery; small white arrows, short gastric branches.

STOMACH

The stomach has two major vascular arcades, one along the lesser curve formed by the right and left gastric arteries and the other along the greater curve, consisting of the right and left gastro-omental (gastroepiploic) arteries.

The left gastric artery usually arises as one of the three major branches of the celiac trunk, originating anywhere from the orifice of the trunk to the hepatic-splenic bifurcation (Figs. 8-4 to 8-6; see also Figs. 8-2 and 8-3). In 2% to 6% of patients, this vessel arises separately from the aorta.^{1,2}

Figure 8-3 Selective left gastric artery injection. L, Left gastric artery; R, right gastric artery (filling retrograde via the left gastric branches); arrows, branches of the left gastric artery supplying the lower esophagus.

Figure 8-5 Celiac arteriogram. a, Anterosuperior pancreaticoduodenal branch; GD, gastroduodenal artery; H, common hepatic artery; i, inferior pancreaticoduodenal branch (filling retrograde via the pancreaticoduodenal arcades); LG, left gastric artery; lo, left omental branch; p, posterior superior pancreaticoduodenal branch; RGO, right gastro-omental artery (the left gastro-omental artery is not well opacified); ro, right omental branch; S, splenic artery; arrowheads, short gastric branches.

Figure 8-6 Early arterial phase, celiac arteriogram. *a*, Anterior superior pancreaticoduodenal branch; *GD*, gastrooduodenal artery; *H*, common hepatic artery; *LG*, left gastric artery; *p*, posterior superior pancreaticoduodenal branch; *S*, splenic artery.

A replaced or accessory left hepatic artery arises from the left gastric artery in 20% to 30% of cases.^{1,2} This has important clinical implications in patients for whom embolization or infusion therapy of hepatic or gastric arteries is anticipated. When this variant is present, the relative blood supply to the stomach and liver can vary, so that minimal supply to either may be present. In about 5% of cases, one or both inferior phrenic arteries arise from the left gastric trunk; this association is much higher when the left gastric artery arises as a separate aortic branch. The importance of this variant is emphasized by the reported association of hypertension and cardiac arrhythmias with vasopressin infusion into the phrenic artery. Accessory left gastric arteries are common.^{1,2}

Because most gastric angiography is performed for GI bleeding, and left gastric arterial ramifications account for about 85% of gastric hemorrhages, this is clearly an important vessel for subselective catheterization. Unfortunately, whereas the celiac artery is most readily catheterized with a caudally directed catheter, the course of the left gastric artery is cephalad. This may make selective catheterization difficult. A number of articles and texts have detailed methods that facilitate catheterization of this sometimes elusive vessel. The basic principle of these procedures is initial selection of the celiac artery with a catheter that has a caudally directed tip, followed by intraceliac exchange for, conversion to, or coaxial insertion of a catheter with a tip that points upward.^{1,2}

The right gastric artery arises at or distal to the common hepatic artery bifurcation, usually from the proper hepatic (57%) but occasionally from the left (17%) or right hepatic (2%) branches or at the origin or proximal portion of the gastroduodenal artery (10%). It has generally been considered an

unimportant vessel for arteriographers, along with the cystic and falciform arteries; however, these small vessels are found to be of increasing concern with the evolution of transarterial chemoembolization and arterial brachytherapy. Because the right gastric and cystic arteries have variable origins, these vessels increase the possibility of nontarget embolization, with subsequent tissue necrosis and/or inflammation (e.g., mucosal ulceration, cholecystitis, skin necrosis).^{1,2}

The right gastro-omental (gastroepiploic) artery is typically the larger of the two gastro-omental vessels (see Figs. 8-2, 8-4, and 8-5). It is the terminal branch of the gastroduodenal artery. The left gastro-omental (gastroepiploic) artery arises from the splenic artery or in conjunction with its inferior splenic branch (see Fig. 8-4). The gastro-omental arteries anastomose in a well-formed arcade along the greater curve of the stomach in 65% to 75% of cases; in most other cases, an anastomosis is still present but is not as well developed. In slightly fewer than 50% of individuals, a parallel anastomotic arcade called the arc of Barkow is present in the greater omentum, joining the right and left omental arteries, branches (respectively) of the right and left gastro-omental arteries (see Figs. 8-4 and 8-5).^{1,2}

The supply from the gastric and gastro-omental arcades is supplemented by other branches. A variable number of short gastric arteries supply the fundus and superior aspect of the greater curve of the stomach, usually arising from splenic hilar vessels (see Figs. 8-4 and 8-5). In 36% to 60% of individuals, a posterior gastric artery arises from the main splenic artery to supply the posterior wall of the stomach and parts of the fundus and gastroesophageal junction. The pyloric region typically receives part of its supply via branches of the gastroduodenal artery.^{1,2}

SMALL BOWEL

Much of the blood supply to the duodenum is via a series of freely anastomosing vessels; the anterior and posterior pancreaticoduodenal arcades provide a rich source of collaterals for the duodenum and head of the pancreas and between the celiac artery and SMA. These arcades (usually dual) form a continuous loop along the descending and transverse duodenum and the pancreatic head. The superior origin of this complex is usually dual, with both branches arising from the gastroduodenal artery and the posterior arcade typically arising more cephalad than the anterior (Fig. 8-7; see also Figs. 8-5 and 8-6). The inferior origin is usually a single trunk, usually arising from the SMA or its first or second jejunal branch (see Figs. 8-5 and 8-7).

Other sources of duodenal perfusion are branches of the right gastro-omental artery, supraduodenal artery (which has many possible origins, including the hepatic artery, gastroduodenal artery, posterior pancreaticoduodenal arcade, and right gastric artery), and smaller gastroduodenal branches.

In addition to the pancreaticoduodenal arcades, another potential collateral route between the celiac and superior mesenteric territories is the arc of Buhler, which represents persistence of an embryologic anastomosis between the celiac and superior mesenteric trunks.

The jejunum and ileum are supplied primarily by multiple branches arising from the left side of the SMA (Figs. 8-8 and 8-9); the level of the ileocolic artery origin is a good general indicator of the division between jejunal and ileal territories. The distal ileum also receives blood from the ileocolic artery (see later). An extensive network of vascular arcades connects

Figure 8-7 Superior mesenteric arteriogram. Enlarged pancreaticoduodenal arcades provide collaterals to the celiac territory in a patient with occlusion of the proximal celiac artery. Inferior pancreaticoduodenal branch (*curved arrows*) arises from the superior mesenteric artery and anastomoses with superior pancreaticoduodenal branches (*straight arrows*) to reconstitute the gastroduodenal artery (G). H, Replaced right hepatic artery arising from the superior mesenteric artery.

Figure 8-8 Superior mesenteric arteriogram. c, Cecal branches of the ileocolic artery; i, ileal branch of the ileocolic artery, anastomosing with terminal branches of the main superior mesenteric trunk; l, ileal branches; IC, ileocolic artery; J, jejunal branches; M, middle colic artery, with branches to the right colonic flexure (r) and the transverse colon (t); s, superior colic branch of the ileocolic artery, supplying the ascending colon and anastomosing with branches of the middle colic artery.

Figure 8-9 Superior mesenteric arteriogram. The middle colic territory (*arrowheads*) is supplied by two anastomosing superior mesenteric branches (M, *arrows*), one of which supplies the right colonic flexure and the other the mid to distal transverse colon. No discrete right colic artery to the ascending colon is present. A, Position of the ascending colon; I, ileal branches; IC, ileocolic artery; J, jejunal branches.

the jejunal and ileal branches; along the mesenteric border of the small bowel, the distal arcades give rise to multiple straight vasa recta that enter the bowel wall. The number of arcades increases, and the length of the vasa recta decreases more distally in the small bowel; these anatomic factors must be considered when performing small bowel embolization.

An important anatomic variant is a persistent vitelline artery, indicating the presence of Meckel's diverticulum. This vessel has a characteristic appearance—a relatively long vessel arising in the ileal region, without anastomoses to other ileal branches and with a network of irregular small distal branches (*Fig. 8-10*). Meckel's diverticulum may also be supplied by ileal branches without a well-defined vitelline artery, although this is less common. A dense mucosal stain at the tip of the diverticulum suggests the presence of ectopic gastric mucosa.

COLON AND RECTUM

The right colon and transverse colon are usually supplied by the SMA. Classically, this supply is described and diagrammed as consisting of three main branches arising independently from the SMA—the ileocolic, right colic, and middle colic arteries. Although the ileocolic is a constant vessel, a true right colic artery (arising independently from the SMA) is uncommon, and the middle colic “artery” is frequently variable in extent and branching pattern, consisting of one or more of five distinct vessels. The discrepancy between the classic description of three main independent branches and the most common situation,

Figure 8-10 Persistent vitelline artery and Meckel's diverticulum. **A.** Selective superior mesenteric angiogram in a patient with recurrent GI hemorrhage shows a characteristic elongated artery (arrows) without anastomoses to adjacent ileal vessels. More proximal vessels show an abrupt change in direction relative to this vessel, reflecting intussusception (inversion) of the Meckel diverticulum. **B.** Surgical specimen of an inverted Meckel's diverticulum.

in which there are two independent branches, has given rise to some confusion and has caused the termination of the SMA to be labeled as the ileocolic artery on angiograms in various anatomic texts. It should be emphasized that the SMA termination is not a colic artery: its branches supply the ileum, and its final terminus joins the ileal branch of the ileocolic artery in a vascular arcade at the ileocecal junction.

The ileocolic artery supplies the transition between the small bowel and colon, with branches to the terminal ileum, cecum, ascending colon, and appendix (see Figs. 8-8 and 8-9). It is the last branch arising from the right side of the superior mesenteric trunk, and its constancy makes it a very important angiographic landmark. Most often, it consists of a main stem branching into two cecal branches distally, with anastomotic branches arising along the main stem. A nearly constant branch of the ileocolic artery is the superior colic, which anastomoses with the next colic artery arising from the SMA, whether the right colic or part of the middle colic complex.

The designation of right colic artery should apply only to an independent branch arising directly from the superior mesenteric trunk that supplies the middle portion of the ascending colon. The midportion of the ascending colon is usually supplied via an arcade formed between the ileocolic artery and middle colic system.

The middle colic artery has been classically described as the major proximal branch of the SMA, which supplies the right colonic flexure and transverse colon. A true middle colic artery is actually seen in slightly fewer than 50% of cases. In other cases, variant arteries or combinations of these arteries supply the vascular territory between the ileocolic or right colic artery and the left colic artery; a single vessel is present 75% of the time (see Figs. 8-8 and 8-9).^{1,2}

The middle colic artery or accessory arteries to the middle colic territory can arise from the celiac, splenic, hepatic, or pancreatic arteries (especially the dorsal pancreatic artery; Fig. 8-11). Thus, angiography of the entire colon may require injection of the celiac artery or its branches.

In unusual situations, portions of the blood supply to the colon can arise directly from the aorta between the origins of the SMA and IMA. In two publications,^{2,3} such a variant has been called the middle mesenteric artery, although in one report the artery supplied the distal transverse and proximal

Figure 8-11 Variant middle colic supply. Celiac injection reveals an enlarged dorsal pancreatic artery (D), from which branches (arrows) arise that course to the middle colic territory and transverse mesocolon.

descending colon, and in the other the artery supplied the entire proximal colon, up to and including the splenic flexure.^{2,3}

The IMA usually supplies the splenic flexure, descending colon, sigmoid colon, and upper rectum IMA (Figs. 8-12 to 8-15). However, the boundary between the parts of the colon supplied by the SMA and IMA can be variable—proximal or distal to the splenic flexure. The IMA terminates in two superior rectal (hemorrhoidal) branches (see Figs. 8-12 and 8-13). It gives off branches from its left side. The first is the left colic artery, which courses toward the splenic flexure (see Figs. 8-12, 8-14, and 8-15). Its branches anastomose with branches of the middle colic territory (see Figs. 8-12 and 8-15). The left colic artery is frequently absent if there is an accessory left colic vessel arising as a portion of the middle colic supply. Other branches arise from the left colic artery or IMA trunk proximal to the superior rectal arteries to supply the descending and sigmoid colon and upper rectum. A colosigmoid artery or branch (see Figs. 8-13 and 8-14) can usually be identified as a large dominant vessel supplying the transition between the descending colon and sigmoid.

Figure 8-12 Inferior mesenteric arteriogram. *L*, Left colic artery; *m*, partial filling of the middle colic territory via the marginal artery; *R*, superior rectal (hemorrhoidal) arteries; *s*, sigmoid branches.

Figure 8-13 Caudal branches of the inferior mesenteric trunk. *CS*, Colosigmoid trunk; *R*, superior rectal (hemorrhoidal) arteries.

Figure 8-14 Inferior mesenteric arteriogram. *CS*, Colosigmoid branch; *L*, left colic artery; *m*, marginal artery; *s*, sigmoid branches; *black dots*, selective catheter.

Figure 8-15 Inferior mesenteric injection. The left colic artery (*L*) ascends toward the left colonic flexure, and the marginal artery (*m*) is opacified in a continuous fashion from the transverse colon to the descending colon.

The marginal artery of Drummond designates a vascular arcade that runs along the mesenteric border of the colon, where it gives off its nutrient vessels (Figs. 8-16 and 8-17; also see Figs. 8-12, 8-14, and 8-15). Defined in this way, the major colic arteries can parallel the marginal artery or constitute part of it; the paracolic arcade can be considered part of the generalized system of paraintestinal arcades present throughout the abdominal GI tract. An enlarged marginal artery frequently provides a collateral pathway between the SMA and IMA territories (see Figs. 8-16 and 8-17). The marginal artery is not always reliably complete along its entire length. Griffith's point, for example, represents a watershed area of a potentially poor anastomotic connection between the SMA territory and marginal artery of the descending colon at the splenic flexure; it is

an area susceptible to ischemic injury when its marginal artery is poorly developed. The arc of Rioloan refers to a more central anastomotic loop that lies within the mesentery, joining the IMA and SMA territories. The term *meandering mesenteric artery* has also been used. This actually represents an enlarged and tortuous left colic artery acting as part of a collateral pathway (see Figs. 8-16 and 8-17).

The more distal rectum is supplied by branches of the internal iliac territory, the middle rectal and inferior rectal arteries. As is the case with the most proximal portion of the gut, angiography of this region is infrequently performed. Collateralization via the rectal arteries between the IMA and internal iliac system can become important in occlusive disease of the aorta and common iliac arteries.

Figure 8-16 Collateral blood supply of the colon. Early (A) and delayed (B) radiographs from an abdominal aortogram show a dilated marginal artery fed by the middle colic artery, which courses along the transverse and proximal descending colon (straight arrows) and reconstitutes the inferior mesenteric artery via the left colic artery (arrowheads in B). Stenosis of the abdominal aorta is present between the origins of the superior and inferior mesenteric arteries (curved arrow in A) and may contribute to diminished flow at the origin of the inferior mesenteric artery.

Figure 8-17 Collateral blood supply of the colon. Early (A) and delayed (B) radiographs from a superior mesenteric arteriogram demonstrate an enlarged marginal artery arising from the middle colic in A (arrows). B. The marginal artery fills the left colic artery (arrowheads) in a retrograde fashion, allowing reconstitution of the inferior mesenteric trunk (curved arrow). The dilated, tortuous collateral pathway has been called a meandering mesenteric artery.

VENOUS ANATOMY

The mesenteric venous system is studied for two main indications: (1) evaluation of the patency of the mesenteric veins in the setting of suspected acute mesenteric ischemia; and (2) evaluation of the patency and direction of flow in the mesenteric, splenic, and portal veins and potential collateral pathways in portal hypertension. Angiography in patients with portal hypertension may be difficult to interpret, and images of high quality are essential. A very good mesenteric venous phase can be obtained using a total volume of 35 mL of nonionic contrast at an injection rate of 5 to 7 mL/s. The use of glucagon (1-mg IV bolus) to slow down the peristalsis and vasodilators to increase the flow improve the quality of the images. Vasodilators may include papaverine (30-mg intra-arterial bolus, followed by a 10-mL saline flush to prevent papaverine crystallization) or tolazoline (Priscoline), 25 mg diluted in 10 mL of normal saline solution, injected slowly for 2 minutes. Contrast medium injection and filming begin immediately after drug administration.

The most important gastric vein is the left gastric, or coronary vein, which courses along the lesser curve of the stomach and joins the splenic-portal venous system at variable sites. It is a frequent pathway for portosystemic collateralization in portal hypertension and splenoportal collateralization in splenic vein occlusion. Gastro-omental and short gastric veins parallel their respective arteries and can be important collateral pathways as well. The superior mesenteric and inferior mesenteric veins run to the right of, parallel to, and drain the respective territories of the SMA and IMA. The superior mesenteric vein joins the splenic vein behind the pancreatic neck to form the portal vein (see Fig. 8-1); the inferior mesenteric vein can join the splenic or superior mesenteric vein or their confluence (Fig. 8-18).

Vascular Diagnosis and Intervention in the Gastrointestinal Tract

PRIMARY VASCULAR DISEASE

Atherosclerotic involvement of the visceral arteries is common, and the angiographic appearance is typical of atherosclerosis in other locations—irregular plaque formation, eccentric or concentric stenosis, and occlusion. Visceral artery stenoses can also occur in other primary vascular disorders, including fibromuscular dysplasia, Takayasu's arteritis, and Behçet's disease, or as the result of response to extrinsic agents, such as ergot preparations. It has been stated that in cases of celiac or SMA fibromuscular dysplasia, the classic string of beads appearance of this entity is less common than that of a tubular stenosis.

Although visceral artery aneurysms usually involve the splenic and hepatic arteries, they can occur in any of the mesenteric arteries. Causes of such aneurysms include arteriosclerosis, medial degeneration, infection (particularly common in the SMA territory), inflammation (particularly pancreatitis), dissection, connective tissue disorders (e.g., Ehler-Danlos type IV), vasculitides such as polyarteritis nodosa (which involves the GI tract in about 50% of cases), IV drug abuse, trauma, and other more unusual conditions (Fig. 8-19). Many are discovered during work-up for GI and intraperitoneal hemorrhage. Aneurysms of the GI tract vasculature may also thrombose and, as a result, present with mesenteric ischemia. Therapy for visceral

Figure 8-18 Venous phase of inferior mesenteric artery injection. The inferior mesenteric vein (I) joins the splenic vein (S). Black dots indicate that the catheter is placed selectively into the inferior mesenteric artery.

Figure 8-19 Polyarteritis nodosa. Multiple small aneurysms, some of which are indicated by arrows, arise from superior mesenteric branches in a patient with polyarteritis nodosa.

aneurysms has traditionally been surgical, but catheter embolization has been used successfully.¹²⁻¹⁷

Aneurysms of the superior mesenteric vein have also been described. Congenital, traumatic, and inflammatory causes have been proposed. Although rare, they may cause abdominal pain, GI bleeding, or compression of adjacent structures.

Arteriovenous malformations, characterized by dilated, tortuous feeding arteries, capillary blush, and prominent venous drainage, can occur throughout the GI tract. Thought to be developmental in origin, they are often seen in younger adults or children. They can be an elusive cause of GI hemorrhage, often discovered only on its angiographic work-up. MDCT has proven useful in the depiction of some of these vascular malformations.

Vascular malformations of the GI tract may also occur in association with systemic disorders such as pseudoxanthoma elasticum, hereditary hemorrhagic telangiectasia, and Klippel-Trenaunay-Weber syndrome. Pseudoxanthoma elasticum is a hereditary, autosomal recessive disorder of connective tissue that involves systemic abnormalities of elastic fibers. Patients display characteristic ocular and cutaneous lesions. Cardiovascular manifestations occur because of fragmentation, degeneration, and calcification of the arterial elastic laminae and premature atherosclerosis. A variety of splanchnic angiographic abnormalities have been described, including angiomatous malformations, vascular tortuosity, segments of vascular narrowing and occlusion, and small aneurysms. Upper GI tract bleeding is common and probably results from submucosal vascular degeneration and inability of the abnormal vessels to constrict at sites adjacent to areas of erosion and hemorrhage. Embolization has been used to treat hemorrhage in this disorder.¹²⁻¹⁸

Patients with hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease) have multiple systemic vascular lesions involving the skin, mucous membranes, and gut. Abnormalities on abdominal visceral angiography include tangled masses of tortuous vessels with early venous filling, direct arteriovenous fistulas, arterial aneurysms, localized venous dilations, and small focal accumulations of contrast medium representing angiomatous lesions that are visualized during the arterial phase of injection of the contrast medium. Thin fragile walls are characteristic of these vascular lesions and help explain their propensity to bleed; recurrent GI hemorrhage is common.

Arteriovenous fistulas of the mesenteric vessels can be congenital or can result from penetrating trauma or from prior abdominal surgery. Successful transcatheter embolization of fistulas involving main mesenteric trunks or branches has been described.

TUMORS

Although rarely used in the primary diagnosis of tumors of the GI tract, angiography will occasionally detect neoplasms as incidental abnormalities or as the cause of active or occult GI bleeding. GISTs (gastrointestinal stromal tumors) are common neoplasms of the upper GI tract and small bowel that have a tendency to bleed. They are typically hypervascular and well defined on angiography (Fig. 8-20); venous shunting is common in GISTs of the small bowel but not typical of those in the stomach. Carcinoid tumors elicit a fibrotic response in the adjacent mesentery that is reflected in a characteristic angiographic appearance of stellate crowding, kinking, and an irregular contour of mesenteric branches. The neoplasm itself is hypovascular but can cause smooth arterial narrowings and occlusions. Venous drainage is typically via multiple collaterals. As might be expected, other processes resulting in mesenteric fibrosis may have a similar appearance.

Adenocarcinomas of the small bowel tend to show signs of encasement without tumor vascularity; in the colon, lesions may be hypervascular. Adenomatous polyps of the colon are hypovascular in most cases, whereas villous adenomas tend to be vascular lesions, with enlarged feeding arteries and draining veins and contrast staining in the parenchymal phase.

Other primary and metastatic upper GI tract tumors, depending on their pathology, may demonstrate nonspecific signs of neoplasia, including neovascularity, vascular encasement, vascular displacement and stretching, and arteriovenous shunting.

INFLAMMATORY DISORDERS

Angiography is seldom used in the work-up of inflammatory lesions such as ulcerative colitis, Crohn's disease, or diverticulitis. Acute inflammation usually produces nonspecific findings, such as increased vascularity with enlargement of feeding arteries, dense capillary blush of the bowel wall, and enlargement and sometimes early opacification of draining veins. In the colon, these findings overlap with those found in early ischemic colitis and may even be normal in the postprandial state. As Crohn's disease progresses, arterial occlusions, irregular arterial

Figure 8-20. Superior mesenteric arteriography in a patient with intermittent arterial bleeding. **A.** Increased vascularity (arrows) is noted in a portion of the jejunum in the arterial phase. **B.** In the late arterial phase, a well-defined tumor stain (straight arrows) is noted, with a dilated early draining vein (curved arrow). A gastrointestinal stromal tumor was diagnosed.

narrowing, and hypovascularity may develop in the involved segment.

ANGIODYSPLASIA OF THE COLON

Angiodysplasia (vascular ectasia) of the colon is a vascular disorder that usually affects the right colon in older individuals. It has a number of characteristic angiographic features, which depend on the stage and size of the lesion—intense and prolonged opacification of a dilated and tortuous mural colonic vein (the earliest sign), vascular tufts (small, densely staining clusters of vessels), and tortuous feeding (Fig. 8-21). To ensure that the early opacification of the draining vein is not simply the result of prolonged arterial injection, it helps to limit the duration of injection of contrast medium to 4 seconds or less.

Although the exact cause is unknown, angiodysplasia may be the result of a degenerative process in which intermittent intramural venous obstruction leads to venous dilation and, later, to direct arteriovenous communication. There is an association of colonic vascular ectasia and aortic stenosis.

MISCELLANEOUS VASCULAR DISORDERS

The effects of radiation therapy on the mesenteric vasculature depend on the time course relative to such therapy. In the subacute phase, a hyperemic blush associated with early venous drainage has been described, correlating with an inflammatory response. In the more chronic setting, radiation enteritis may

produce obliterative findings, with irregular stenoses or occlusions of mesenteric branches, as well as findings related to shortening of bowel length, including tortuosity and vascular crowding.

Abnormalities of bowel position, although not typically diagnosed by angiography, may also be observed in the angiographic work-up of abdominal symptoms. Findings in conditions such as intussusception, internal hernias, and volvulus include unusual displacement of vessels, abrupt angulation and overlapping of branches, and abrupt changes in vessel caliber.

ACUTE GASTROINTESTINAL BLEEDING

The management of acute GI bleeding has become common practice in any active interventional radiology service. Diagnostic and therapeutic angiography is generally used after endoscopic techniques have failed to control the bleeding source. Acute upper GI bleeding is better evaluated first by endoscopy. In a large percentage of cases, endoscopy will be effective in controlling the acute problem. If endoscopic techniques fail for any reason, the endovascular option is the next step; however, the diagnostic input from the endoscopic procedure is essential to the interventionalist. For example, if endoscopy shows a large, uncontrollable variceal bleed, the option of choice will probably be a transjugular intrahepatic portosystemic shunt (TIPS) procedure or a balloon-occluded retrograde transvenous obliteration (BRTO). If the source of bleeding is an esophageal tear or gastric or duodenal ulcer, arterial evaluation is in

Figure 8-21 Angiodysplasia of the right colon.

A. Angiogram in a patient with intermittent lower GI hemorrhage demonstrates a vascular tuft (arrowheads) and paired vessels (arrows), indicating early draining veins adjacent to colonic arterial branches. **B.** Prominent draining veins (arrows) are opacified later in the angiogram. **C.** Colonoscopic view demonstrates an abnormal tuft of vessels in the right colon in a patient with GI hemorrhage.

order. Gastric ulcers may be managed with superselective embolization of the left gastric artery and esophageal ulcers and Mallory-Weiss tears by assessment of the lower esophageal arteries; duodenal ulcers are usually managed with assessment of the gastroduodenal artery.

Lower GI bleeding requires a different approach. Acute lower GI bleeding may be difficult to evaluate endoscopically without the proper patient preparation; in those cases, diagnostic and therapeutic arteriography may be the first choice. Small bowel and colonic bleeds are managed with superselective transcatheter embolization of the vasa recta of the affected field.¹⁹⁻²¹ Lower GI bleeds demand more technical skill and require superselective embolization of the vasa recta of the involved territory (Fig. 8-22). The use of microcatheters, microcoils (0.018-inch systems), and microparticles (polyvinyl alcohol [PVA] and spheres) has allowed the interventional specialist to manage these difficult and clinically challenging cases, with a success rate that ranges from 80% to 100% and low recurrence rates ranging between 5% and 15%.^{19,21}

Acute Mesenteric Ischemia

CLINICAL AND ANGIOGRAPHIC FEATURES

MDCT has become the major imaging method for assessing patients with acute abdominal pain. Because it can evaluate the bowel wall, the surrounding mesentery, and major vascular structures, MDCT can often suggest the presence of mesenteric ischemia or infarction and depict the thrombus if it is sufficiently large and central. Angiography provides detailed anatomic and etiologic information necessary for the urgent management of mesenteric ischemia and, in addition, allows for the initiation of selective transcatheter therapy, when appropriate.

Lateral abdominal aortography reveals the status of the proximal mesenteric vessels and should be the initial step in the angiographic evaluation of mesenteric ischemia. If the proximal

portion of the SMA is patent, selective arteriography of this vessel is performed for a detailed study of the superior mesenteric trunk and its branches and of the mesenteric venous drainage. Acute mesenteric ischemia is primarily a disorder of the SMA territory, and selective celiac and inferior mesenteric injections are not usually necessary. However, these further studies can provide information about the presence and extent of collateral supply to the superior mesenteric territory, particularly when the chronicity of a superior mesenteric occlusion is questioned. This additional angiography can also be considered if clinical data strongly suggest involvement of the stomach, duodenum, or segment of colon supplied by the IMA.

Major causes of acute mesenteric ischemia are SMA thrombosis or embolism, mesenteric venous thrombosis, and the non-occlusive form of ischemia. Vasculitis, aortic or mesenteric arterial dissection, trauma, bowel strangulation, and other disorders are less common causes of mesenteric ischemia. Involvement of all or most of the SMA territory typically produces severe and life-threatening mesenteric ischemia. Focal ischemia can result from more limited or segmental forms of the previously mentioned causes and has less severe clinical manifestations.²²⁻²⁷

SMA occlusion with embolism is more common than thrombosis (Figs. 8-23 to 8-26). The angiographic distinction between these two entities can be difficult. Multiple filling defects, tracking of contrast medium at the lateral aspects of a filling defect, and convex menisci protruding into the opacified vascular lumen suggest emboli. Emboli also tend to lodge at vascular branch points, generally more distally than an occlusive thrombus, which typically forms in the vicinity of a preexistent atherosclerotic stenosis of the proximal SMA. At times, however, emboli can lodge at proximal stenoses, or an embolus can initiate more proximal or distal propagation of thrombus. Extramesenteric emboli are common in cases of embolic mesenteric ischemia.²²⁻²⁷

Mesenteric venous thrombosis accounts for up to 10% to 20% of cases of acute mesenteric ischemia. Causes of this

Figure 8-22 Acute diverticular bleed in the sigmoid colon. **A.** Selective inferior mesenteric angiogram in a patient with acute lower GI bleed. The selective IMA injection shows no active bleeding. **B.** Repeat selective injection of contrast shows a definite area of extravasation in the superior hemorrhoidal territory (arrow). **C.** Arteriogram obtained after superselective embolization with a single 6-mm × 7-cm Nester, 0.018-inch microcoil (Cook, Bloomington, IN) shows no further extravasation (arrow).

Figure 8-23 Superior mesenteric embolus. A nearly occlusive filling defect (arrow) is present in the main superior mesenteric artery trunk, with tracking of contrast medium around it and patency of the more distal superior mesenteric artery.

Figure 8-25 Superior mesenteric embolus. Abrupt occlusion (arrow) of the superior mesenteric trunk is present distal to jejunal branches in a patient with atrial fibrillation.

Figure 8-24 Superior mesenteric emboli. Multiple filling defects (arrows) are present in the superior mesenteric artery branches in a patient with atrial fibrillation.

disorder include bowel obstruction, hypercoagulable states, portal hypertension, abdominal inflammatory disease, previous surgery (particularly splenectomy), and trauma. Often, no predisposing condition is identified. Patients may present with less severe illness than in other forms of acute mesenteric ischemia; recognition that major venous occlusion does not always result in ischemia has increased as more cases of mesenteric venous thrombosis have been identified with the use of cross-sectional imaging. MDCT has excellent sensitivity for the diagnosis. However, angiographic recognition remains important as part of the favored algorithm for acute mesenteric ischemia. On superior mesenteric arteriography, slowing of arterial flow is noted, with prolonged staining of the bowel wall and smaller mesenteric arterial branches. Arterial vasoconstriction may be present. Normal mesenteric veins fail to opacify or show filling defects; venous collaterals may be visualized.²²⁻²⁷

Anatomic vascular obstruction need not be present for mesenteric ischemia and infarction to occur. Diminished cardiac output, systemic hypotension or hypovolemia, and some pharmacologic agents, particularly digitalis, can result in severely diminished intestinal blood flow, presumably mediated by vasoconstriction of the mesenteric arteries. Nonocclusive mesenteric ischemia accounts for a substantial proportion of cases of acute mesenteric ischemia (see Fig. 8-26). On angiography, intense vasospasm is characteristic. Spasm is frequently irregular or segmental, with more severe areas of narrowing often seen at the origins of arterial branches. Regular and diffuse spasm can also occur. Contrast medium flows sluggishly through mesenteric vessels, causing delayed opacification of peripheral and mural branches. In this regard, the findings are similar to those of mesenteric venous thrombosis, although normal veins eventually fill in most cases of nonocclusive ischemia. Increased reflux of contrast medium into the aorta can also be seen,

Figure 8-26 Nonocclusive mesenteric ischemia. **A.** Diffuse mesenteric arterial spasm is present, with poor filling of smaller arterial branches. **B.** Improvement in the spasm is noted after initiation of an intra-arterial papaverine infusion.

reflecting increased impedance to mesenteric flow. In practice, this finding is usually judged subjectively, although more objective and quantitative means of assessing superior mesenteric flow based on aortic reflux have been described.

Despite improved methods of diagnosis and therapy for acute mesenteric ischemia, this disorder continues to be associated with a high mortality rate. In the late 1970s, Boley and colleagues²¹ described their aggressive approach to acute mesenteric ischemia that remains the standard of care. Although about 50% of patients presenting with the full syndrome of acute mesenteric ischemia still die, this approach represents a distinct improvement compared with earlier controlled studies that showed only 10% to 30% survival; in addition, the aggressive approach may allow more bowel to be salvaged in those who survive. Key features of this approach include maintenance of a high level of suspicion for the disorder, followed by prompt diagnosis and therapy with emergency angiography.²²⁻²⁷

Another feature of the aggressive algorithm is the selective infusion of vasodilators into the SMA, the rationale being that vasospasm is associated with acute mesenteric ischemia, not only the nonocclusive variety but also occlusive forms (see Fig. 8-26). When mesenteric angiography reveals vasospasm or arterial occlusion, a test dose of a vasodilator should be given.

THROMBOLYTIC THERAPY FOR MESENTERIC VASCULAR OCCLUSION

In most cases of acute mesenteric ischemia with major vascular occlusion, the rapid deterioration of bowel status with time and the need to resect infarcted bowel mandate prompt surgical therapy (Fig. 8-27). However, a number of case reports have suggested a potential role for transcatheter thrombolytic therapy or mechanical thrombectomy (via a transhepatic route) in selected cases of recent mesenteric vascular occlusion, either alone or, as with vasodilator therapy, as part of a combined treatment approach. Candidates for this therapy have included patients deemed unlikely to survive major surgery because of coexistent disease, those with minor or partial vascular occlusions or mild symptoms (who, it could be argued, might need only observation, conservative therapy, and possibly

Figure 8-27 Chronic mesenteric ischemia. Superior mesenteric arteriogram of a 62-year-old woman with intermittent episodes of abdominal pain reveals a severe superior mesenteric artery stenosis (arrow). There is filling of the celiac territory via an enlarged pancreaticoduodenal arcade (arrowheads; the inferior pancreaticoduodenal artery arises from the superior mesenteric artery proximal to the stenosis). The presence of the collateral flow attests to the occlusion of the celiac origin, as also noted with lateral aortography. Symptomatic relief occurred after patch angioplasty of the superior mesenteric artery and aorta to celiac artery bypass with an autologous vein.

anticoagulation), those with extensive portal or mesenteric venous thrombosis precluding surgical thrombectomy or bypass, and those who develop occlusion of mesenteric arterial grafts. The presence of peritoneal signs suggesting bowel necrosis is considered a contraindication to thrombolytic therapy alone.

Chronic Mesenteric Ischemia

Chronic mesenteric ischemia is characterized by the presence of severe abdominal pain, typically 30 to 40 minutes after meals. This abdominal pain results in significant weight loss secondary to decreased food intake. Typically, the patients complain of so-called eating fear. In most cases, these patients undergo extensive diagnostic work-ups to investigate the cause of abdominal pain, including upper and lower endoscopies, MDCT, and abdominal ultrasounds, which are negative or disclose no reasonable cause of the pain presented by the patient. A vascular cause for the abdominal pain is typically a diagnosis of exclusion and is usually demonstrated on MDCT or magnetic resonance imaging (MRI) obtained to investigate the abdominal pain.

Most authors agree that at least two major vessels have to be involved or affected (celiac trunk, superior mesenteric artery, or inferior mesenteric artery) to consider that the patient's abdominal pain is actually caused by a vascular problem, but in some cases only one vessel is involved and treatment of a single artery may be sufficient to palliate or improve the patient's symptoms (Fig. 8-28). Angioplasty of celiac or SMA stenotic lesions has been replaced by repair using endovascular stents. The technical success rate for endovascular stent placement in the celiac trunk and/or SMA approaches 100%, with a clinical success approaching 85%. As in other vascular territories, stent stenosis may develop, and these patients require frequent surveillance of their stents.

A very interesting entity is arcuate compression of the celiac trunk, or median arcuate ligament syndrome. This is more common in young women and is characterized by nausea, diarrhea, weight loss, and postprandial abdominal pain. The characteristic picture is that of a compression of the cranial aspect of the celiac trunk, approximately 1 to 1.5 cm distal to the ostium of the artery (Fig. 8-29). This anatomic compression of the celiac trunk may be identified by CT, MRI, or angiography.

Angiographic diagnosis is classic for this entity; a two-view lateral aortogram is performed, one view in inspiration (which releases the compression and almost gives the artery a normal appearance) and a second view with the patient in full expiration (which tightens the compression and makes the stenosis evident; see Fig. 8-29). The clinical significance of this anatomic finding is controversial because only a single vessel is involved. The management is surgical; endovascular techniques are not indicated. The clinical response to surgery, in highly selected patients, is 60% to 70%. Angioplasty or stent placement may have a role if a stenosis of the celiac trunk persists after surgery.

Bowel Interventions

REASONS FOR PLACEMENT OF NEEDLES OR CATHETERS INTO THE GASTROINTESTINAL TRACT

This section is presented as a response to the question of why radiologists might place needles or catheters into or through portions of the GI tract.

Inadvertent Catheterization of the Bowel

This relates not to a specific indication but to a complication that has been described in the setting of various abdominal interventions, specifically unintentional puncture and placement of tubes into or through the bowel. The underlying principle of management (see later) is that given intrinsically normal bowel with no distal obstruction, intestinal contents will flow preferentially along the intestinal lumen. When inadvertent catheterization occurs, treatment of the complication should include drainage of any adjacent infected fluid. Antibiotics, bowel rest, and extended catheter drainage (to allow an organized tract to form) should permit safe catheter withdrawal; at this point, the site of perforation should seal readily because of muscular contraction of the bowel wall.

Figure 8-28 Chronic mesenteric ischemia—endovascular stent placement. **A.** Digital subtraction aortogram in a 67-year-old man with severe abdominal pain and a history of 25-pound weight loss. The arteriogram shows a prominent arc of Riolan, bilateral common iliac artery stenosis, and bilateral renal artery stenosis. **B.** Lateral aortogram confirms the presence of a severe stenosis of the superior mesenteric artery. **C.** Lateral aortogram after a successful endovascular stent placement shows an excellent angiographic result.

Figure 8-29 Celiac artery compression. Nonselective lateral aortograms in expiration (**A**) and inspiration (**B**) show the typical appearance of celiac artery compression by the arcuate ligament. Note how the compression of the celiac trunk is barely noticeable in the inspiration arteriogram.

Transenteric Biopsy and Fluid Aspiration

Frequently, the bowel is interposed along potential paths for percutaneous diagnostic aspiration of fluid collections or biopsy of masses. Transgression of the bowel in these cases, as well as during therapeutic drainage, can sometimes be avoided by injecting physiologic saline solution or carbon dioxide to displace structures. Nevertheless, avoidance of the bowel is not always possible. Because the aspirating needle passes through a colonized space, with increasing bacterial counts the more distal the segment of the GI tract, the potential for contamination must be acknowledged; confounding of culture results in fluid aspiration or leakage of contaminated contents along the path of the needle. The former may be aided by Gram stain of fluid because a contaminated sample will tend not to have a cellular response. With regard to the latter, considerable clinical and laboratory experience seems to indicate that transgression of the bowel wall with fine needles rarely leads to clinically evident infectious complications. As with any interventional procedure, the risks of bowel puncture should be balanced against the risks of alternate diagnostic methods and the need to obtain a pathologic or microbiologic diagnosis. Although it seems prudent to choose an approach that avoids the bowel, particularly the colon, and although it seems reasonable to avoid larger cutting needles if the bowel must be punctured, the need to pass a needle through the bowel does not in itself constitute a contraindication to needle aspiration. Possible exceptions would include passage through an obstructed loop or through the bowel in an immunosuppressed patient, although little hard data exist in these settings.

Puncture of Bowel to Confirm Identity

At times, nonopacified bowel loops may mimic abnormal fluid collections; conversely, collapsed loops may mimic masses (e.g., in the case of afferent loops in patients with a history of GI malignancy). Percutaneous puncture of such indeterminate structures with thin needles and injection of water-soluble contrast medium can be invaluable in guiding further diagnosis and therapy. Contrast medium is injected through one of the needles as it is withdrawn; if the bowel has been crossed, the needles can be withdrawn and another path chosen.

Drainage of Fluid Collections Shielded by Bowel

Taking the concept of transenteric diagnostic aspiration a step farther, and mimicking traditional surgical therapy (e.g., pseudocystogastrostomy) to some extent, transenteric drainage of infected or inflammatory fluid collections has been proposed (Figs. 8-30 to 8-33). This has been an area of particular interest in the setting of pancreatitis, which is often associated with lesser sac collections unapproachable for percutaneous drainage, except through the stomach. Although this approach is controversial, its advocates argue that it can help avoid spillage of pancreatic enzymes around the drainage site and prevent formation of pancreaticocutaneous fistulas. Along the same lines, there is growing favorable experience with transrectal drainage of pelvic collections by standard catheter placement or a one-step, complete aspiration. This approach offers increased patient comfort and possibly decreased complications compared with the more standard transgluteal drainage route.

DIAGNOSTIC BIOPSY OF BOWEL MASSES

Several investigators have found sonographic and fluoroscopic (via barium studies) biopsy of pathologic processes directly involving the bowel wall to be effective and safe. Indications for this approach include the following: (1) lesions yielding no diagnostic tissue via endoscopic biopsy (a common problem with submucosal lesions); (2) lesions in patients who are poor candidates for endoscopy or open exploration; (3) lesions that because of their location are not accessible endoscopically; and (4) lesions that if proved malignant will obviate the need for further investigation or change in therapy.^{28,29}

ENTERIC PUNCTURE FOR DIAGNOSTIC OR THERAPEUTIC ACCESS

An uncommon but potentially very useful application of transenteric access is to allow diagnostic or therapeutic access to various structures. One example of this is access to GI tract strictures difficult to reach via a nasenteric or rectal approach. Another novel approach involved placement of a percutaneous

Figure 8-30 Abscess drainage. This patient had a history of lye-induced esophageal and gastric injury; a colonic interposition and coloenteric anastomosis were carried out.

A. After the patient presented with fever and nausea, a left upper quadrant abscess was drained under CT guidance. A drainage catheter (arrowheads) enters an abscess cavity containing contrast medium. **B.** Sinogram obtained via drainage catheter (arrowheads) shows an irregular abscess cavity (straight arrows) that communicates with the bowel (curved arrows). **C.** After 8 weeks of catheter drainage, contrast medium injection results in spill (arrows) along the tract to collect on the skin surface; there was no filling of bowel. The catheter was removed without recurrence of earlier symptoms.

Figure 8-31 Abscess drainage, multiple catheters. Bowel injury was discovered at laparotomy in a patient who had abdominal trauma.

A. Sinogram obtained immediately after abscess drainage. The drainage catheter (arrowheads) enters an irregular cavity (straight arrows); no filling of bowel is noted on initial injection. The curved arrow indicates a surgical drain. **B.** Three drainage catheters have been placed 10 days later, two in the lower portion of the abscess cavity (curved arrows) and one in its cephalad aspect (straight arrow). Filling of the bowel (black dots) is now apparent. **C.** The abscess cavity has almost completely collapsed 3 months later, but a fistula to the bowel (arrowheads) is still present. Two catheters remain in place (arrows). With continued drainage, the fistula eventually closed and the catheters were removed.

Figure 8-32 Percutaneous drainage of an esophageal leak. Sinography performed after CT-guided drainage of a juxtalesural fluid collection (arrowheads) shows communication with the esophagus (arrows).

Figure 8-33 Percutaneous drainage of a diverticular abscess. A drain (arrow) courses through the anterior abdominal wall and enters the abscess, which has been opacified with contrast medium. The patient underwent a single-stage surgical resection after successful abscess drainage.

cecostomy tube to allow diagnostic and therapeutic endoscopy of the small bowel in a patient who was bleeding from ileal angiodysplasia.

Transenteric access to the biliary tract can be used in those in whom a choledochojejunostomy or hepaticojejunostomy was previously performed. Advantages of this approach are that it allows repeated access to the biliary tract without the need to traverse liver parenchyma, it gives a mechanical advantage for patients in whom multiple sites of disease need to be treated

(e.g., sclerosing cholangitis), and it allows easier access when the biliary tract is nondilated. Surgical techniques anticipating these advantages have been designed to allow easier access to the relevant bowel loop. Initially, this consisted of a formal jejunostomy, or so-called Hutson-Russell loop. Although access to the bowel was guaranteed, problems with skin excoriation caused by leakage of bile or mucus developed. Subcutaneous tacking of the jejunal loop was another option, but this was plagued by subcutaneous inflammation in the early postoperative period and by peristomal hernias later on. Consequently, the favored approach at this time is subparietal tacking of the loop, whose site can be marked with surgical clips.

Puncture is generally performed with fluoroscopic guidance (by identification of the gas within the loop), although opacification could potentially be obtained with manipulation of a nasoenteric tube.

Enteral Access for Bowel Decompression

Whereas percutaneous gastrostomy is most frequently used to provide a route for enteral alimentation, it can also serve as an effective means of decompressing the bowel in patients with chronic intestinal obstruction and symptoms of nausea and vomiting, eliminating most of the complications associated with long-term nasogastric intubation. However, this subset of patients may present unique technical problems, mainly the result of more limited access to the stomach because of diffuse peritoneal carcinomatosis, adhesions from prior radiation or surgical therapy, or ascites. Gastrostomy has also been used to provide symptomatic relief in patients with gastroparesis or delayed gastric emptying in the absence of a fixed anatomic obstruction.

Direct, percutaneous, small bowel catheterization has also been used to treat symptoms of enteric obstruction or stasis in cases in which gastric decompression alone would not suffice. These situations usually require surgery, but percutaneous management can be considered an alternative for patients who are poor surgical candidates. Maneuvers designed to distend or fix the bowel are often not possible, nor are they likely to be necessary because significant intrinsic distention of bowel is present. Acute palliation and long-term prevention of recurrence of closed loop obstruction in a patient with metastatic colon carcinoma have been described. Symptoms of blind or afferent loop stasis have also been relieved by this method. An alternative approach in afferent loop syndromes has been percutaneous management; a drainage tube can be passed percutaneously into the liver or gallbladder and through the biliary tree into the affected bowel limb (Fig. 8-34). A possible benefit of this route is simultaneous drainage of the biliary tract because these patients may have associated biliary stasis or cholangitis. The occurrence of delayed septic shock in one patient in whom transhepatic treatment of an afferent loop was performed suggests that placement of a separate biliary drain may be advisable. In appropriate circumstances, feeding tubes have been placed via a transhepatic biliary route. It is important in such cases to infuse feeding solutions through a tube placed well beyond the native or postsurgical biliary-enteric junction.

In nonobstructive colonic distention, the cecum is usually the most severely involved segment. This finding demonstrates the Laplace law, in which the portion of colon with the greatest diameter (the cecum) responds first with further distention once intraluminal pressure begins to increase. Cecal ileus refers to the situation in which cecal distention develops out of

proportion to that of the remainder of the colon. These patients have a mobile cecum suspended on a mesentery. When the patient is in the supine position, the cecum can rotate anteriorly, leading to progressive distention.

Massive colonic distention, when left untreated, may lead to colonic perforation, ischemia, peritonitis, and death. Once massive distention (≥ 9 cm) of the cecum occurs, the risk of perforation seems less related to the absolute degree of distention than to the duration of distention. Therefore early recognition and therapy for this condition are critical.

The initial treatment of nonobstructive colonic distention is conservative; it includes placement of a nasogastric tube, withholding of oral intake, and treatment of underlying metabolic and other medical disorders. If the distention fails to improve, colonoscopy and colonic decompression tube placement should be attempted; a fluoroscopic approach to decompression using

a coaxial steerable system for intubation has been described. These methods may prove ineffective because of thick retained stool. Distention may recur after initial colonoscopic success.

After unsuccessful colonoscopic decompression, surgical cecostomy has been the next therapeutic approach. However, surgery in these patients, who are often seriously ill, can be risky. Consequently, a number of investigators have attempted percutaneous decompression of the massively dilated but unobstructed cecum. Successful decompression has been achieved with simple aspiration and drainage tube placement. Reports of percutaneous decompression of the mechanically obstructed colon have also appeared.

A variety of approaches, methods, and tube sizes have been used for percutaneous cecostomy (Fig. 8-35). Usually, fluoroscopy provides sufficient guidance, although CT may be helpful if there are questions about the approach. Both the trocar and Seldinger methods of tube placement are feasible for these patients. Although further experience with percutaneous cecostomy is necessary to assess risks fully and evaluate optimal technique and indications, this is an alternative method of colonic decompression in severely ill and debilitated patients. Also, cecostomy has also been used to treat fecal incontinence in children by allowing antegrade cleansing enemas to be administered.³⁰⁻³²

Enteral Access for Alimentation

The last but not most common and important indication for radiologic enteric access is for nutritional support. Most of these procedures are percutaneous gastrostomies and gastrojejunostomies, but percutaneous jejunostomy and duodenostomy have been used in increasing numbers.³³⁻³⁸

In the short term, nasoenteric tubes can be used effectively for alimentation. However, longer term use is associated with a variety of problems. These tubes are uncomfortable and often psychologically untenable for patients. Also, they predispose the patient to gastroesophageal reflux, esophagitis, and stricture formation, and the luminal diameter of most nasoenteric tubes is small, predisposing them to occlusion.

Total parenteral nutrition is another option for feeding patients. It is particularly useful for patients who are unable to assimilate enteric nutrients or require bowel rest. As a general method for alimentation, however, it has disadvantages

Figure 8-34 Percutaneous cholecystostomy. Patient with pancreatic carcinoma, after Roux-en-Y cholecystojejunostomy and gastrojejunostomy, who developed abdominal pain, elevated serum bilirubin level, and septicemia. CT revealed a dilated afferent bowel loop anastomosed to the gallbladder. Percutaneous cholecystostomy with passage of a catheter via the gallbladder (arrow) and into the jejunal loop (arrowheads) resulted in improvement of symptoms.

Figure 8-35 Percutaneous cecostomy. A transperitoneal approach was used. **A.** CT scan. **B.** Abdominal plain film. Air (arrows in **A**) was introduced into the peritoneal cavity during the procedure.

compared with the enteral route. It is more costly than the enteral alternative. Over the long term, it is associated with several complications, including small bowel atrophy, abnormalities of hepatic function, and electrolyte disturbances. The need for prolonged venous access also places the patient at high risk for the development of venous thromboses and stenoses.

Enteral access, on the other hand, is associated with few complications once it is established and is less expensive than total parenteral nutrition. Thus, enteral alimentation is indicated for patients with longer term nutritional requirements who, because of mechanical, functional, or psychological disorders, are unable to meet their nutritional needs without assistance but can still assimilate enterically administered nutrients.

In the past, gastrostomy tubes were placed surgically. However, many patients who require gastrostomy tubes are poor operative risks because of malnutrition, debilitation, and coexistent illnesses. Gastrostomy has increasingly been performed using less invasive techniques, such as radiologic, endoscopic (percutaneous endoscopic gastrostomy), and laparoscopic methods. Although each method has certain advantages and disadvantages, there has been little randomized prospective comparison among them. As much as in any area of interventional radiology, local referral patterns, politics, and expertise may result in widely variable patterns of practice among institutions.

There are several other technical differences. Radiologic gastrostomy or gastrojejunostomy appears to be less costly than the surgical alternative, does not require general anesthesia, and has less associated postprocedural ileus. The endoscopic method does not require exposure to ionizing radiation and can be performed easily and rapidly at the bedside. Although bedside placement using ultrasonography or portable fluoroscopy is possible, it is rarely performed. Endoscopic placement may be difficult or impossible when there is obstruction or high-grade narrowing of the esophagus or pharynx, leaving imaging-guided placement as the only feasible nonoperative alternative. Imaging guidance may also be critical for delineating and avoiding interposed structures (e.g., the colon) between the anterior abdominal wall and stomach. In patients prone to aspiration, imaging guidance is usually preferable because endoscopy may require heavy sedation and may be a lengthy procedure if tube placement into the jejunum is required. Tubes placed under imaging guidance seem less likely to give rise to stomal wound infections than those inserted endoscopically. The endoscope must pass through the contaminated oral cavity rather than the scrubbed anterior abdominal wall. Finally, endoscopic placement offers the possibility of biopsy and other diagnostic methods when appropriate.

Percutaneous gastrostomy can be performed by a variety of methods. Before the procedure, the patient should be given nothing by mouth for at least 12 hours to minimize risks of aspiration and peritoneal leakage. Prophylactic antibiotics are usually not necessary. Only mild sedation combined with local anesthesia at the puncture site is generally required, although general anesthesia offers advantages in infants and younger children.

An entry site is chosen in the anterior left upper quadrant, which allows direct puncture of the stomach, with no transgression of bowel, liver, or vascular structures. Preprocedural ultrasonography or CT delineates these structures (Fig. 8-36). Ultrasound is quickly and easily performed in the fluoroscopy

Figure 8-36 CT-guided percutaneous gastrostomy. **A.** CT scan of the upper abdomen in a patient with pseudomyxoma peritonei attributable to ovarian carcinoma shows the stomach (arrow) surrounded by adjacent organs and peritoneal metastases. **B.** At a more caudal level, a safe window to the stomach is present. Percutaneous gastrostomy was successfully performed under CT guidance. Arrowheads, Gastric lumen; black arrow, initial puncture needle.

suite and is often used routinely to demarcate a safe window on the skin surface. Another helpful adjunct in patients who have no obstruction or altered enteric motility is the administration of oral contrast medium the night before the examination, which provides good opacification of the colon at the time of the procedure.

One potential hazard of percutaneous gastrostomy is injury to the inferior epigastric artery, which lies at the junction of the medial two thirds and lateral third of the rectus abdominis. Therefore skin puncture should be made at a site lateral to this muscle or close to the midline of the abdomen, depending on the position of the stomach. A subcostal puncture site usually provides good access to the stomach, is more comfortable for the patient, and avoids pleural and pulmonary complications.

Gastric distention makes it easier to pierce the gastric wall, which tends to invaginate and move away from the puncture needle. Distention also helps bring the stomach closer to the anterior abdominal wall and displaces any interposed bowel.

Distention is provided by insufflation of the stomach with several hundred milliliters of room air administered via a previously placed nasogastric tube. If a nasogastric tube cannot be placed, the stomach can be punctured with a Seldinger needle, and air can be injected through its lumen. Another means of providing distention is the oral administration of effervescent granules that produce carbon dioxide. IV glucagon (1.0 mg in adults, 0.14 mg/kg in children) can be used to augment these measures by diminishing gastric peristalsis and decreasing passage of air through the pylorus. If fluoroscopic puncture proves difficult because of interposed structures or variant anatomy, inability to pass a nasogastric tube, or inability to tolerate gastric distention, cross-sectional imaging can also be used for guidance (see Fig. 8-36).

Another option for providing distention is intragastric inflation of a latex balloon attached to the end of a nasogastric tube. The balloon is inflated with diluted contrast medium or air, providing an easily visualized and stable target for fluoroscopically or sonographically guided puncture. Bursting of the balloon confirms intragastric positioning of the needle tip. Although this device can be difficult for some patients to tolerate and is usually unnecessary, it may be helpful when simple insufflation is unsuccessful in providing gastric distention, as seen in patients with a partial gastrectomy.

The anterior wall of the stomach is usually punctured in its middle third, toward the side of the greater curvature (Fig. 8-37). The greater and lesser curvatures should be avoided because the larger vascular arcades of the stomach are located in these regions. Lateral fluoroscopy is used to access the

Figure 8-37 Fluoroscopically guided percutaneous gastrostomy. The midbody of the gas-filled stomach has been punctured with an 18-gauge Seldinger needle (*curved arrow*). It is angulated toward the pylorus, and a wire has been manipulated into the proximal jejunum. A gastrojejunostomy tube was subsequently placed. A nasogastric tube was used for insufflation of air (*straight arrow*).

proximity of the anterior gastric wall to the skin surface. If initial or delayed small bowel catheterization is anticipated, a downhill puncture angled toward the pyloric region makes manipulations of the guidewire and catheter easier. Too great an angle, however, makes tract dilation and catheter exchange difficult. If the tube is being placed for decompressive purposes only, it can be angled somewhat more vertically and toward the gastric fundus. Once the gastric wall is indented by the puncture needle, a short vigorous thrust is used to pierce its muscular layers.

Final catheter placement can be achieved by a variety of methods. One is the Seldinger technique and its variants, in which initial puncture is made with an 18- to 22-gauge Seldinger needle or a small sheathed needle. A wire is passed through the sheath or cannula, and successive guidewire and catheter exchange is used to place a final gastrostomy tube. Techniques using a trocar, an instrument consisting of a catheter or sheath mounted on the puncture needle, have also been successfully used in placing gastrostomy tubes. The trocar technique allows larger and softer tubes to be inserted at the time of the initial procedure and requires fewer catheter and wire exchanges, each of which may result in loss of gastric access. The initial puncture, however, may be difficult and risky with trocars, which are usually larger devices.

When the Seldinger technique is used, a peel-away sheath may facilitate insertion if catheter exchange is difficult or placement of a soft catheter or catheter without an end hole is desired. In addition, removal of the peel-away sheath may correct any gastric wall invagination that has occurred. During passage of catheters or dilators, the stabilizing guidewire has a free end within the GI tract and must not be displaced out of the gastric lumen. A method of preventing this problem in children has been described. The free end of the wire is secured and pulled from the stomach to the mouth by a wire basket or snare, allowing stable control of both ends of the wire in a manner analogous to that of endoscopic methods. In general, however, these maneuvers are unnecessary.

The use of fixation devices as an adjunct to percutaneous gastrostomy has generated some controversy. These devices are fasteners that can be placed through a small needle to affix the anterior gastric wall to the anterior abdominal wall at one or more sites. Advocates of these devices have cited a number of potential advantages, including reduced intraperitoneal leakage of gastric contents, facilitation of guidewire and catheter exchange and immediate placement of large catheters, increased safety in patients expected to have difficulty with track maturation (e.g., patients on corticosteroid therapy), easy reinsertion in cases of early catheter dislodgment (of greater concern in uncooperative patients), and possible tamponade of gastric hemorrhage induced at the gastrostomy site. Theoretical disadvantages of gastric fixation are interference with gastric peristalsis and excessive traction on the gastric wall, resulting in pressure necrosis, bleeding, infection, or catheter dislodgment. Problems related to excessive traction are not unique to the use of fixation devices. Other potential disadvantages that can be obviated by careful technique include anchor misplacement into the peritoneal cavity and difficulty with tube passage immediately adjacent to the anchor. Most of the controversy, however, has arisen because of extensive clinical and laboratory experience with percutaneous gastrostomy accomplished without fixation devices, which suggests that the procedure can be performed easily, safely, and less expensively in most cases.

without their use. No large prospective comparisons have yet been made.³³⁻³⁸

Massive ascites is generally considered a contraindication to percutaneous gastrostomy. Large quantities of peritoneal fluid make gastric puncture difficult and can lead to tube dislodgment, gastropexy breakdown, peritonitis, and skin breakdown. However, gastrostomies have been safely placed and managed in patients with smaller amounts of ascites via a combination of gastropexy, preprocedural paracentesis, and regular postprocedural paracentesis to allow the enterostomy track to mature.

Another area of controversy is the final position of the tube. Some practitioners prefer that the tube be manipulated into the proximal jejunum at the time of the initial procedure. This allows for immediate catheter feeding, diminishes the risks of gastroesophageal reflux and aspiration of gastric contents, and provides additional insurance against catheter dislodgment. Other practitioners have maintained that routine gastrojejunostomy is not indicated, and they have reserved jejunal placement for patients who are prone to reflux or aspiration, have impaired gastric motility, or have partial gastric obstruction. Scintigraphy has been reported to be helpful in determining whether a patient can safely tolerate a gastrostomy tube without risk of reflux and aspiration. Even if the tube is left in the stomach initially, subsequent conversion to a gastrojejunostomy tube can usually be accomplished without difficulty as long as the original angle of puncture is toward the pylorus. If not, a stiff sheath can frequently be used to redirect the tube, although in cases of severe unfavorable angulation, a new access site may be the best approach. A large variety of tubes have been used for percutaneous gastrostomy, including simple Cope loop catheters, Foley catheters, and catheters specially designed for percutaneous gastrostomy and gastrojejunostomy. Catheter sizes usually range from about 12 to 20 Fr. Because of its ease of insertion, the Cope loop is preferred by many investigators, except in patients who require gastrojejunostomy.

Altered gastric anatomy caused by prior surgery, although it may sometimes preclude percutaneous gastrostomy, should not be considered an absolute contraindication. However, a full understanding of the postsurgical anatomy is important. Generally, gastrostomy can be performed with minor modifications of standard methods, such as the use of longer needles and craniocaudal fluoroscopy. Other techniques reported to be helpful in this setting include gastric balloon support and the use of a transhepatic catheter route guided by CT.

Potential complications of percutaneous gastrostomy include catheter dislodgment, pericatheter leakage, peritonitis, sepsis, pain, hemorrhage, inadvertent puncture of other organs, pulmonary aspiration, subcutaneous inflammation, and wound infection. Although patients should be observed carefully after percutaneous gastrostomy for signs of complications, it should be noted that a number of postprocedural radiologic findings are common and should not by themselves cause alarm or prompt laparotomy. These findings include pneumoperitoneum and small abdominal wall and gastric hematomas. Subcutaneous emphysema, gastric pneumatosis, free or loculated intraperitoneal fluid, and pneumoperitoneum that increases in volume are uncommon and should be viewed with more concern (Fig. 8-38).

Long-term care of percutaneous gastrostomy catheters includes keeping the catheter entry site clean and maintaining tube patency after feeding with injection of saline solution. A

Figure 8-38 Percutaneous gastrostomy: complication. CT scan obtained 3 days after percutaneous gastrostomy. Although pneumoperitoneum (arrowheads) is often seen in the absence of clinically apparent complications, findings of loculated (straight arrow) and free (curved arrow) intraperitoneal fluid are atypical and are cause for concern. Peritoneal spillage in this case resulted from intraperitoneal positioning of a side hole of the gastrostomy tube. The patient required surgical treatment.

tract between the abdominal wall and gastric lumen is usually well established in about 7 days, and exchange of an occluded tube or replacement of a recently dislodged tube after this time is generally easy. If the tube is inadvertently removed at an earlier time, an attempt can be made to recatheterize the tract, but it is less likely to be successful. As noted earlier, one possible advantage to using gastric fixation devices is that it facilitates tube replacement or repeated puncture of the stomach in this early period. If pericatheter leakage is noted, the problem may respond to replacement of the tube with one that is slightly larger. Delayed pericatheter hemorrhage, presumably attributable to erosion into an adjacent vessel, has been described. Successful tamponade and long-term control of the bleeding can be achieved with gentle traction by a Foley catheter against the gastric wall. Another delayed complication, occurring from days to months after gastrostomy placement, is perforation of the GI tract by the tube. Perforations can be managed with nonsurgical means, including tube replacement, antibiotic therapy, drainage of associated abscesses, and gastric compression.

Direct percutaneous catheterization of the small bowel has been performed much less often than percutaneous gastrostomy. The procedure is made difficult by the mobility and compliance of small bowel loops and by the difficulty associated with providing and maintaining their distention. Although fluoroscopic guidance has been used in many cases, CT and ultrasonography have also proved useful for localization and puncture of the small bowel.³⁹

Indications for percutaneous jejunostomy include the need for prolonged enteric feeding in patients in whom a gastrostomy by the percutaneous or endoscopic route is not possible. This can occur, for example, when a large hiatal hernia is present or in postsurgical patients after a gastric

pull-up procedure or partial gastrectomy with a small and high-positioned gastric remnant. Other potential indications include chronic aspiration, gastric outlet or duodenal obstruction, recurrent dislodgment of previously placed gastrostomies, retrograde gastrojejunostomy dislodgment back into the stomach, or premature dislodgment of a jejunostomy.

Adequate distention of the jejunum is an important facet of the procedure. Transnasal or transoral intubation of the small bowel can provide access for small bowel distention with air, contrast medium, or supportive balloons. Direct fine-needle puncture and air insufflation into the left upper quadrant can also be used to identify the jejunum.³⁹

Mesenteric Vasculature

Summary

Computed tomography angiography (CTA) revolutionized vascular imaging when vessels smaller than 1 mm in diameter were imaged with single-slice spiral CT.¹⁻⁵ However, because of the small volume of coverage and limitations in the speed of image processing, CTA did not become widely used until the introduction of multidetector CT (MDCT) in 1998.⁶⁻⁸ With the advent of MDCT, temporal and spatial resolution of the scanners significantly improved.^{9,10} Gantry rotation times of 0.33 to 0.5 second, with slice thicknesses of 0.5 to 0.75 mm, are now available on most MDCT scanners.

CTA uses several parallel detectors along the z-axis with multiple channels of data (currently up to 320), allowing significant improvement in z-axis resolution. This allows isotropic resolution for most vascular applications with images obtained during a single, short breath-hold. The result has been elimination of the trade-off between spatial resolution (z-axis) and scanning range, a significant limitation of single-detector spiral CT.^{11,12} Hence, a significant benefit has been a paradigm shift from single-slice to volumetric data acquisition. This, in turn, has made imaging of different vascular phases with a single contrast bolus a reality.⁷

Other than its limited invasiveness, advantages of CTA include lower cost and a potential reduction in the total volume of contrast material administered. With the fastest scanners currently available (16, 64, 256 slice), abdominal CTA can be performed with as little as 50 mL of contrast material using a saline flush.^{13,14} This requires meticulous attention to the timing of contrast bolus (see later). In the evaluation of life-threatening vascular disease, such as traumatic aortic injury or pulmonary embolus, CTA has clear advantage because of short acquisition times.¹⁵

An important advantage of CTA over catheter angiography is its ability to examine the vessel wall, as well as its lumen. The adjacent organs can also be evaluated (e.g., staging of pancreatic adenocarcinoma). Another advantage of CTA is its ability to

evaluate a vessel in projections that cannot be obtained with conventional techniques.

The increased use of CT has led to significant increases in radiation exposure and concerns about its effects.¹⁶ CT currently accounts for approximately 75% of the total radiation dose delivered by medical imaging.¹⁷ A number of techniques have been developed to help reduce radiation exposure from abdominal CTA. These technologic innovations address the issue in several ways, including collimation of x-ray beams to reduce exposure from over beaming, newer reconstruction algorithms, automatic tube current modulation, and use of lower tube potential settings.¹⁶ Automatic tube current modulation automatically adjusts the current during scanning to decrease the amount of radiation in anatomic regions that do not require higher current (e.g., lung bases or above the iliac crest) while maintaining image quality.¹⁶ In the appropriate setting, abdominal CTA may be performed with a reduced kilovoltage (kV) setting to decrease radiation to the patient and improve signal-to-noise ratio.¹⁸ For example, recent studies have demonstrated that lowering the kVp setting from 140 to 80 kVp significantly reduces patient dose and improves the contrast-to-noise ratio in the aorta while maintaining an acceptable level of image noise.¹⁹ Scanning with lower tube voltage may facilitate reduction of intravenous contrast dose because of an improved contrast-to-noise ratio.²⁰⁻²³

Technical Considerations

Until the introduction of 16- and 64-slice CT scanners, improvement in spatial resolution came at the cost of temporal resolution. Now, with faster gantry rotation time (0.27 to 0.5 second) and an increase in the number of detector rows, isotropic voxel acquisition independent of the length of coverage is possible. The newer CT scanners use very complex spiral cone beam reconstruction algorithms instead of the filtered back projection mathematical reconstruction algorithm that was used in older scanners. These mathematical reconstruction algorithms are a byproduct of significant advances in computer technology. A combination of all these advances has made isotropic scanning of the abdominal aorta and its branches in a single breath-hold a clinical reality.^{7,12,24}

The latest generation of image reconstruction brings many other benefits in addition to improved spatial and temporal resolution. Although filtered back projection is a widespread and fast reconstruction algorithm used to create CT images, this technique produces relatively noisy images when the tube current or voltage is lowered. Iterative reconstruction (IR), the newest improvement in reconstruction algorithms in CT, can remove the noise from low-dose images using mathematical models.²⁵ IR has shown the potential to improve image quality, allowing substantial reduction in patient dose compared

with the filtered back projection techniques (Fig. 9-1).²⁵⁻³¹ More recent studies have demonstrated that IR facilitates a reduction in administered contrast dose while maintaining image quality when using a low-dose technique.²¹

With shortened acquisition times of the multislice scanners, optimizing and maximizing vascular enhancement has become more challenging.^{32,33} CT angiography requires excellent contrast enhancement of the targeted vessels. A good-quality CT angiogram requires an arterial density value greater than 200 Hounsfield units (HU).^{34,35} This should be achieved rapidly, and the peak should coincide with the acquisition interval. Therefore it is crucial to time the contrast bolus correctly. However, rapid administration of contrast material shortens the plateau phase of contrast enhancement, thus creating a further challenge for correct timing of the study.^{32,33,36} For most abdominal CTA applications, an injection rate of 4 to 5 mL/s yields optimal vascular enhancement.

For achieving rapid intravenous (IV) administration of contrast material, excellent IV access (18- or 20-gauge needle) and a dual-head power injector are required. A saline bolus via a dual-head injector following contrast administration prolongs and improves arterial enhancement; it also decreases the amount of contrast required by using the residual contrast in the tubing, patient's arm veins, and superior vena cava.^{14,37,38}

There are several factors that affect time to peak from the start of a contrast bolus. These include the iodine content of contrast material, injection rate, and patient's cardiac status.^{32,33,37,39} A faster injection rate, for example, can achieve a higher density in the targeted vessel and results in a higher quality CTA. It also separates the arterial from the portal venous phase and thus results in excellent image quality without cross-contamination by different phases.³² Contrast material with a higher iodine concentration improves vascular enhancement if all other parameters are held constant.^{32,40} Because several factors affect time to peak enhancement in the aorta, a fixed timing delay for image acquisition is not advised.

All modern CT scanners provide software for calculating the optimal time to start scanning after the administration of a test bolus, a so-called test bolus injection (Fig. 9-2A) or allow automatic image acquisition once a preset HU threshold in the target vessel has been reached, known as bolus triggering (Fig. 9-2B). An important consideration with the 16- and 64-slice scanners is the possibility of outrunning the contrast bolus in patients with low cardiac output or in cases that require long z-axis coverage (e.g., combination of extremity and abdominal CTA). To overcome this problem, one can slow down the scanner by increasing the gantry rotation time and slowing the table speed.^{41,42}

Figure 9-1 CT angiography of the abdominal aorta with lower kV and iterative reconstruction algorithm. **A, B.** Axial and coronal maximum intensity projection images of the abdominal aorta obtained with 120 kV, tube current modulation, and filtered back projection reconstruction algorithm before aortic graft revision. Density of the aorta is 312 HU, with an image noise of 33. The dose-length product is 631 mGy • cm. **C, D.** Follow-up study after revision of the aortic graft was obtained with 80 kV, tube current modulation, and an iterative reconstruction algorithm. The density of the aorta has increased substantially to 574 HU whereas the image noise is similar, at 33. The dose-length product has decreased to 301 mGy • cm.

ROI	Peak (HU)	Times to peak(s)	Sample (HU) at 18.0 s
1	147.3	18.0	147.3

Figure 9-2 Graphic depictions of contrast bolus timing methods.

A. Test bolus injection technique. With this technique, a small bolus of contrast material (usually 15 to 20 mL) is administered, followed by a saline chase of similar volume. Time to peak is calculated after the acquisition of several images, with the region of interest placed on the target vessel. **B.** Bolus triggering technique.

A region of interest is placed on the target vessel and injection of contrast material is started. After reaching the preset threshold (100 HU in this case), the scanner automatically instructs the patient to hold his or her breath and image acquisition takes place automatically. With the bolus triggering technique, less contrast material is used because a test bolus is not needed.

As noted, the new multislice scanners, in combination with dual-head injectors, allow for a marked decrease in the amount of contrast used for routine CTA. However, the total volume of contrast administered for a routine abdominal CT (usually 150 mL of contrast material at a concentration of 300 mg/mL) should not change if solid organs, such as the liver, are evaluated in conjunction with CTA. Lowering the total volume of contrast may potentially reduce the sensitivity of lesion detection.^{12,40}

Many authors had previously reported the use of gadolinium chelates for CTA in patients who have diminished renal

function.⁴³⁻⁴⁶ Although gadolinium is radiodense and may be used as a contrast agent with an x-ray, many gadolinium-based products have higher osmolality than iodine-based contrast media and are therefore potentially more nephrotoxic. More importantly, there have been several reports of nephrogenic systemic fibrosis leading to serious physical disability in patients with end-stage renal disease who had been receiving gadolinium-containing contrast agents.⁴⁷⁻⁴⁹

Image Processing

Thinner slice acquisition with CTA has resulted in a significant increase in the number of images acquired. Hence, data overload has been a direct side effect of isotropic and near-isotropic scanning. CTA of the abdominal aorta and its branches on the newest scanners generates over 1000 images.⁵⁰ As the volume of data significantly increases, the processing power of many of the current image processing workstations is pushed to its limits. The strain on the fiberoptic networks and image processing workstations has become a significant challenge for many institutions that have installed the fastest CT scanners. Workflow and image transfer issues are significant byproducts of CTA that are beyond the scope of this discussion but are important to consider when upgrading to the latest CT technology.

Postprocessing of the source data not only improves visualization of the vascular structures and their relationship to the adjacent organs, but also decreases the number of slices needed for review of the dataset.^{51,52} Images can be processed on the scanner or a free-standing image processing workstation. Thicker slices may be produced for review of the axial images on the picture archiving and communications system (PACS).⁵³ Volume rendering, maximum intensity projection (MIP) rendering, or multiplanar reconstructions are routinely used to display large datasets.^{7,54} Volume-rendering techniques use attenuation thresholds to create a volumetric display of data and allow visualization of different tissue types simply by changing threshold settings. MIP rendering does not provide spatial depth but improves visualization of smaller vessels. Most institutions, including ours, routinely use a combination of the MIP and volume-rendered display of data for CTA because these two are complementary. Although volume rendering is useful for the display of soft tissues and three-dimensional relationships, MIP provides a more detailed view of the vessels within the slab of data and is less operator-dependent.⁵⁴

Anatomy

The major branches of the abdominal aorta are readily visible on helical CT and CTA. However, to evaluate vascular disease, CTA with thin sections and sufficient contrast enhancement is required. The typical branching of the celiac artery to the common hepatic, left gastric, and splenic arteries can routinely be appreciated on CTA. The smaller branches arising from the common hepatic artery may also be evaluated by CTA if thin slices are acquired and contrast enhancement is optimized by bolus timing or tracking techniques. The superior mesenteric artery and its branching are also easily evaluated by CTA. A significant portion of patients studied with CTA demonstrate variations in the branching of the abdominal aorta.⁵⁵⁻⁵⁸

The renal arteries arise at approximately the L1-2 level, caudal to the origin of the superior mesenteric artery and cephalad to the origin of the inferior mesenteric artery. In approximately 28% of patients, there are multiple renal arteries.⁵⁹

The venous structures in the abdomen can also be evaluated by CTA. However, timing of scanning will be different, depending on the venous structure imaged. Renal veins will rapidly enhance as they return blood to the inferior vena cava. This, in combination with unopacified blood from the lower extremities, can create a pseudothrombus in the inferior vena cava. For optimal imaging of the portal vein, a delay of 65 seconds after the start of contrast administration is required. Therefore, to perform CTA and CT portography, one has to scan the abdomen successively with the newest multichannel scanners because these scanners, in combination with the rapid administration of contrast material, allow complete separation of the arterial and venous phases of hepatic enhancement. This separation of phases is more difficult with single- and four-slice MDCT because of lower temporal and spatial resolution. With the latest 16- and 64-channel scanners, early and late arterial enhancement of the liver can be imaged separately.

The portal vein arises from the confluence of the superior mesenteric and splenic veins and branches into right and left branches at the hepatic hilum. The right portal vein divides into anterior and posterior branches. The left portal vein defines the boundaries of the segments II, III, IVa, and IVb. When portal hypertension is present, numerous venous collaterals may be visible on MIP and volume-rendered images. The inferior mesenteric vein can be followed parallel to the course of superior mesenteric vein in the lower abdomen, coursing anterior to the left renal vein and draining into the splenic vein.

Anatomic variations of the major branches of the abdominal aorta, inferior vena cava, portal vein, and renal veins are common and are visible on CTA. For example, an accessory hepatic vein may be seen between segments V and VI. Single retroaortic or duplicated left renal veins are seen in 2.5% and 9% of the population, respectively. CTA allows accurate mapping of these variants.^{55,60,61} Assessment for these variations is essential when evaluating for hepatic segmentectomy, using the Whipple procedure, hepatic or renal donor assessment, or bowel resection. This is discussed in detail later in this chapter.

Figure 9-3 Intramural hematoma. **A.** Unenhanced image of the upper abdomen shows hyperattenuating aortic intramural hematoma (arrows). **B.** Enhanced image of the upper abdomen shows thrombus in the aortic wall, which can mimic chronic aortic thrombus or periaortic fluid.

Clinical Applications

Common abdominal applications of CTA include evaluation of the abdominal aorta, preoperative and postoperative assessment for renal and liver transplantation, preoperative planning for hepatic segmentectomy and pancreatic surgery, mesenteric ischemia, and gastrointestinal (GI) hemorrhage. Other applications include cholecystectomy and splenectomy planning, as well as assessment for renal arterial disease in the evaluation of hypertension. The protocols for each application should be individually tailored to optimize imaging of the targeted vascular structures. For example, planning a Whipple procedure should include arterial and portal venous phase images.

ABDOMINAL AORTA

MDCT has revolutionized imaging of the abdominal aorta because of its excellent spatial resolution and advantages over direct catheter angiography (DCA) (described earlier). Because of these advantages, CTA is usually the preferred imaging modality for evaluation of the abdominal aorta in acute and nonemergent settings.^{9,10,62,63}

Aortic Dissection

CTA allows accurate depiction of intimal separation from the adventitia and its extension into branch vessels. The site of intimal tear and its extension determine prognosis. Most institutions use the Stanford classification to assess prognosis as type A dissections (involving the ascending aorta), which require surgical management, and type B dissections (confined to the descending aorta), which are often managed conservatively.

Full assessment of aortic dissection by CTA requires unenhanced CT followed by contrast-enhanced CT. Unenhanced CT is useful because the detection of a dense intramural hematoma may be mistaken for chronic thrombus on enhanced images (Fig. 9-3). On enhanced images, extension of the intimal flap to the aortic side branches and perfusion of organs affected by dissection should be assessed. Although quite variable, the true lumen is usually anterior to the false lumen in the upper abdominal aorta. At the level of the renal arteries, the false lumen usually supplies the left renal artery. The false lumen can also be distinguished from the true lumen by its larger diameter, which also shows lower attenuation if images are acquired during peak arterial enhancement. If there are iatrogenic or

spontaneous fenestrations of the intima, the false lumen may show enhancement similar to that of the true lumen (Fig. 9-4). Complications of aortic dissection include hemorrhage, hypoperfusion of the involved organs, and aneurysm formation.

Aortic Aneurysm

An abdominal aortic aneurysm (AAA) is a fusiform or focal saccular dilation, usually of the infrarenal portion of the aorta, more than 4 cm in external anterior-posterior diameter.⁶⁴ About 90% of AAA are infrarenal, with most limited to the abdominal aorta, but extension to the common iliac arteries does occur. Accessory renal arteries may arise from an infrarenal aneurysm, thus affecting management. About 10% of aneurysms are juxtarenal, involving the main renal arteries, or suprarenal, involving the celiac or superior mesenteric arteries. Suprarenal and infrarenal aortic aneurysms together form a dumbbell configuration.

Aortic aneurysms are frequent in the older population and can be a cause of sudden death if they rupture.⁶⁵ The prevalence of AAA is estimated at 1.5% of those older than 50 years and 5% to 8% of men older than 65 years.^{66,67} Because rupture of an aortic aneurysm can be catastrophic, aggressive screening and treatment have been advocated.⁶⁸ An untreated AAA larger than 5 cm in diameter has a 20% likelihood of rupture in 5 years.⁶⁹

Ultrasound has been advocated as the imaging modality of choice for AAA screening.^{70,71} However, it has several shortcomings, including variability in transverse dimensions of the aneurysm, limitations in aneurysm neck assessment, and limited visualization of luminal thrombus.⁷² Because of the inherent limitations of ultrasound, CTA is preferred for confirming diagnosis, characterizing the aneurysm, and preoperative planning.^{73,74}

Currently, there are two accepted methods of treatment for AAA, open surgical repair and an endovascular approach.⁶⁵ Open surgical repair is associated with significant risk, including a 6% to 10% mortality rate that is commonly caused by myocardial infarction.^{67,75,76} Endovascular aneurysm repair (EVAR) is a technique that was first described by Parodi and colleagues in 1991.⁷⁷ This method excludes the aneurysm by traversing it with a stent graft, thus reducing pressure on the aortic wall.⁷⁸ The results of this less invasive treatment have been excellent, with fewer complications and more rapid recovery.^{79,80}

Preoperative assessment of the aorta is preferably performed with multislice CTA because accurate measurement of the diameter of the aneurysm, its length, and its relationship to major vessels (e.g., renal arteries) is essential.⁸¹⁻⁸³ For EVAR planning, the diameter and angle of the aneurysm neck, as well as its relationship to the renal arteries, is evaluated. Also, the amount of luminal clot may affect treatment. Three-dimensional evaluation of the aneurysm is particularly helpful for treatment planning (Fig. 9-5).⁸⁴ CTA provides useful information regarding femoral access sites and aortic accessibility.⁸³ Orthogonal measurements of the aneurysm using a center line provide accurate measurements for preoperative planning. CTA has been shown to be extremely accurate for measuring vessel lengths, diameters, and angles and for assessing occlusive disease and calcification.⁸⁵

Patients treated with EVAR undergo frequent imaging by CTA to monitor for endoleaks, stent migration, fracture, and stability of aneurysm size (Fig. 9-6).⁸⁶ An increase in the diameter of an aneurysm is associated with endoleak. Evaluation of an endoleak historically required imaging with unenhanced CT and imaging during the arterial and venous phases of contrast enhancement (Fig. 9-7). Unenhanced images are used to detect

Figure 9-4 Type A aortic dissection. **A.** Volume-rendered image. The false lumen has a larger diameter and lower density. Note the higher density of the contrast material in the distal portion of the false lumen because of fenestration in the intima, which is better seen on the transverse image. **B.** Maximum intensity projection image shows the left renal artery being supplied by the false lumen. Intimal dehiscence (arrow) allows perfusion of the left kidney.

Figure 9-5 Infrarenal abdominal aortic aneurysm. Volume-rendered image shows relationship of the aneurysm neck to the renal arteries (arrows). The distance from the renal arteries using vessel analysis software and center line measurements should be calculated before EVAR. Incidentally noted is the replaced left hepatic artery arising from the left gastric artery (arrowhead).

Figure 9-7 Stent graft placement for abdominal aortic aneurysm. There is opacification of the excluded portion of the abdominal aortic aneurysm (arrowheads) by a type II endoleak (arrow). The endoleak may be better visualized during the venous phase of the study.

Figure 9-6 Endovascular stent graft. Orthogonal images allow assessment of the stent lumen.

artifacts from calcification or embolization material that may mimic endoleak on enhanced images. Venous phase images have been shown to enhance detection rate of endoleaks. In a type I endoleak, there is a leak in the proximal or distal end of the graft. Type II endoleaks are caused by retrograde flow from aortic side branches, commonly the inferior mesenteric or lumbar arteries. Type III endoleaks are related to separation of the graft components and require immediate treatment. Type IV endoleaks have been associated with leakage through the graft pores and are usually transient. Reintervention is recommended for any type I or III leak⁸⁷; type II endoleaks are characterized by lower flow and thus tend to be monitored regularly with intervention only if there is a significant increase in aneurysm size.^{88,89}

More recent studies on EVAR follow-up with CTA have focused on methods for radiation dose reduction. Although monitoring has typically involved triphasic protocols, some have suggested that the arterial phase can be eliminated, using only unenhanced and venous phases. This technique has been shown to depict and classify endoleaks accurately, with a significant dose reduction.^{90,91} Dual-energy CT is another more

recently described alternative for endoleak detection that may lead to lower radiation exposure.⁹¹⁻⁹³ Dual-source CT scanners contain two x-ray tubes with two corresponding detectors arranged on the gantry at a 90-degree angular offset.⁹⁴ When used in the dual-energy mode, the two x-ray tubes operate at different peak voltages, enabling reconstruction of virtual unenhanced images from a single venous phase acquisition.⁹⁵

PANCREAS

Staging of pancreatic cancer with multiphasic CT is now the standard of care in many institutions.⁹⁶ It requires arterial, parenchymal, and portal venous phase images to evaluate the solid organs and mesentery (Fig. 9-8).⁹⁷⁻⁹⁹ Addition of a noncontrast phase allows detection of parenchymal and vascular calcifications. Neutral oral contrast agents help distend the bowel and improve visualization of the bowel wall. Positive oral contrast agents (e.g., iodine-based agents) obscure vascular detail and should be avoided in all abdominal CTA procedures.

Although curved multiplanar reformations of the pancreas improve visualization of the parenchyma and pancreatic duct, MIP and volume-rendered images are needed for vascular analysis (Fig. 9-9).^{100,101} The newest generation of scanners allows rapid multiplanar and MIPs on the scanner, thus obviating the need for routine data transfer to an independent image processing workstation.

Staging of the pancreatic carcinoma is discussed in detail in Chapter 98. Because of the frequent variations of vascular anatomy that can affect the surgical approach, close evaluation of the anatomic variants, in addition to tumor encasement of the adjacent vasculature, is essential. For example, the presence of a replaced right hepatic artery originating from the superior mesenteric artery can significantly alter the planning for a Whipple procedure because this vessel traverses posteriorly to the pancreatic head (Fig. 9-10). Similarly, preoperative knowledge of a replaced left hepatic artery facilitates ligation during a left hepatectomy because this major branch does not need to be identified in the porta hepatis.¹⁰²

Figure 9-8 CT angiogram for the staging of pancreatic carcinoma. A large infiltrating pancreatic mass (large arrows) is encasing the superior mesenteric and common hepatic arteries (small arrows) and occluding the splenic vein (arrowhead). Note the perigastric collateral veins.

KIDNEYS

CTA is routinely used for the preoperative planning for nephrectomy, diagnosing renal artery stenosis, and evaluating renal artery in-stent restenosis and ureteropelvic junction obstruction.¹⁰³⁻¹⁰⁶ CTA has been shown to be extremely accurate for the assessment of renal artery stenosis and other renal vascular pathologies. Although CTA and magnetic resonance angiography (MRA) are equally accurate for the assessment of significant renal artery stenosis,¹⁰⁷ MRA cannot accurately assess the lumen of most renal artery stents because of susceptibility artifacts or regional flow dephasing, even with contrast administration.¹⁰⁸⁻¹¹⁰ Furthermore, contrast-enhanced MRA in patients with impaired renal function is limited by the risk of nephrogenic systemic fibrosis and the difficulties

Figure 9-9 Volume-rendered image of pancreatic carcinoma (long arrow) with involvement of the portal vein. Note irregularity and subtle narrowing of the portal vein (arrowheads). A biliary stent is in place (short arrow).

Figure 9-10 CT angiogram for staging of pancreatic head carcinoma. Shown is the replaced right hepatic artery (arrow) arising from the superior mesenteric artery (arrowhead).

in evaluating vascular calcifications.¹¹¹ However, the application of 64-slice CT to renal artery angiography has been reported to yield excellent results for the detection of native renal artery stenosis¹¹² and renal artery in-stent restenosis.^{106,113}

CTA is useful when evaluating potential renal transplant recipients through the use of multiplanar reformations, MIP images, and volume rendering.¹¹⁴ To perform an arterial anastomosis, a site without significant arteriosclerosis must be chosen. In nondialysis patients with significant chronic renal insufficiency and patients receiving peritoneal dialysis, only nonenhanced scanning is performed because residual renal function may be damaged by the use of IV contrast. MIP imaging is useful for showing vascular calcifications, leading to the production of a vascular map. Conversely, in patients on hemodialysis, nonenhanced and arterial phase imaging are performed. MIP images permit visualization of small branch vessels, but luminal narrowing can be overestimated because of vascular calcifications.¹¹⁵ Thus, MIP images are compared with the acquired axial images to determine the true degree of stenosis.¹¹⁶ Volume rendering allows better demonstration of a vascular map in these patients because vessel lumen and mural calcifications can be individually defined¹¹⁷; therefore the degree of stenosis can be accurately measured.¹¹⁸ Volume rendering also allows color display, which may improve comprehension of the 3D relationships of different anatomic structures.¹¹⁹

CTA is the imaging technique of choice for the evaluation of potential renal donors.¹²⁰ Its role is to assess vascular anatomy and evaluate for renal pathology (Fig. 9-11). A comprehensive examination includes noncontrast images to evaluate for renal calculi and vascular calcification and the arterial phase to detect vascular anatomic variants and anomalies, nephrographic phase

to detect renal parenchymal abnormalities, and excretory phase to evaluate the collecting systems and ureters.^{61,104,121,122} Coronal, thin slab MIP images are useful for optimal visualization of the renal arteries.¹²³ Because MIP images do not provide spatial depth, volume-rendered images are also beneficial (Fig. 9-12). It is feasible to scan the renal vasculature with 50 mL of non-ionic iodinated contrast material and a saline chase using a dual injector on a 16- or 64-slice CT, with excellent results.¹⁴ To improve opacification of the ureters, however, a saline bolus or diuretics may be beneficial.¹²⁴

LIVER

Vascular complications are a significant contributor to morbidity following hepatic surgery. The hepatic surgeon greatly benefits from vascular mapping of the liver when planning tumor resection, laparoscopic surgery, or transplantation (Fig. 9-13). Until rather recently, catheter angiography was the standard diagnostic method for preoperative planning of hepatic surgery. However, its associated morbidity and suboptimal visualization of the venous structures have made CTA the new standard in many institutions. CTA provides exquisite hepatic vascular detail and allows evaluation of the liver parenchyma and other organs.^{55,56}

When planning any type of hepatic surgery or locoregional therapy, knowledge of the vascular anatomy variation is essential. Accessory and aberrant hepatic venous and arterial branches are common and are easily visualized by CTA.^{55,125} CTA has been shown to be as effective as catheter angiography in planning a selective hepatic arterial infusion of chemotherapy.⁵⁷

MESENTERIC VASCULATURE

CTA allows excellent visualization of the mesenteric vasculature (Fig. 9-14).¹²⁶ Aneurysms, thrombosis, stenosis, dissection, and inflammatory processes affecting the mesenteric vasculature

Figure 9-11 CT angiogram for evaluation of potential renal donor. **A.** Small accessory right renal artery (arrow). **B.** There are also two right renal veins (arrowheads).

Figure 9-12 Volume-rendered images of CTA performed for renal donor evaluation. There are two left renal arteries (arrows). Also, note the replaced common hepatic artery arising from the superior mesenteric artery, as well as a small accessory left hepatic artery arising directly from the aorta (arrowheads).

Figure 9-13 Patient with metastatic hemangiopericytoma evaluated for resection. **A.** A large very vascular hepatic mass (arrows) is displacing the stomach. **B.** The mass is supplied by a replaced left hepatic artery (arrow) arising from the left gastric artery. Accurate vascular mapping resulted in uneventful resection of the mass.

Figure 9-14 CT angiogram of the mesenteric vessels.

have been evaluated by MDCT. CTA is a robust method for evaluation of acute and chronic bowel ischemia (Fig. 9-15). However, because of its high temporal resolution, it may be necessary to scan the region of interest twice because a “pure” arterial phase does not allow evaluation of the venous structures. This is necessary because incomplete enhancement of the mesenteric venous branches during the late arterial phase may mimic thrombosis.

Atherosclerotic disease is a common cause of chronic mesenteric ischemia and is better assessed with CTA than with contrast-enhanced MRA because of its high spatial and temporal resolution.¹²⁷ Chronic mesenteric ischemia has many

different nonatherosclerotic causes, such as fibromuscular dysplasia, median arcuate ligament syndrome, many forms of vasculitis (including Takayasu’s arteritis, polyarteritis nodosa, and segmental mediolytic arteriopathy), and connective tissue diseases, such as Ehlers-Danlos syndrome. CTA is an excellent modality when evaluating vasculitides because of its ability to assess luminal narrowing, including stenosis and occlusion, aneurysmal dilation, and vascular wall changes such as wall thickening and enhancement.¹²⁷ Compression of the celiac axis by the median arcuate ligament is referred to as median arcuate ligament syndrome and may cause abdominal angina (Fig. 9-16). Also, this entity has been reported to predispose patients who have undergone orthotopic liver transplantation to develop hepatic artery thrombosis. Although surgical treatment can lead to clinical improvement in symptomatic patients, the importance of celiac artery compression in asymptomatic patients has not been established. If median arcuate ligament syndrome is suspected, imaging should be obtained during full inspiration to avoid artifactual stenosis.^{128,129} Celiac and mesenteric stenoses are best visualized by sagittal thin slab MIP or volume-rendered images (Fig. 9-17). Thin slab coronal MIP images also provide an excellent overview of the mesenteric vascular structures and the bowel loops.¹³⁰ The use of neutral oral contrast agents is important when evaluating the mesentery to improve visualization of the bowel mucosa.

Acute mesenteric ischemia is a life-threatening event that may have various causes. These include embolic phenomena, severe hypoperfusion, thrombosis of stenotic vessels, dissection, hypercoagulable states, and vasculitis. As noted, the diagnosis of mesenteric venous thrombosis requires delayed images to avoid early-phase, incomplete enhancement. Unenhanced images are also beneficial because they may show a hyperdense thrombus.^{7,131} The classic angiographic hallmark of an embolic occlusion—the abrupt termination of a vessel (cutoff sign)—and a luminal filling defect, indicating a nonocclusive thrombus, are both demonstrable with CTA. Mesenteric CTA is helpful when evaluating acute superior mesenteric artery (SMA) ischemia by localizing the site of occlusion, thus indicating the underlying cause of ischemia, because thrombosis of the SMA typically occurs within 2 cm of its origin, whereas embolic occlusions occur more distally.¹²⁷

When evaluating for mesenteric vascular pathology, close attention to the morphology of the bowel is important because

Figure 9-15 Occlusive thrombus in the superior mesenteric artery. **A.** Volume rendering shows defect in the superior mesenteric artery (arrows). Note the aortic stent graft. **B.** Sagittal reformatted image better demonstrates the occlusive thrombus (arrowheads) in the superior mesenteric artery.

Figure 9-16 Compression of the celiac artery by the median arcuate ligament (arrow).

Figure 9-17 Thrombus in the superior mesenteric artery (arrow) in a patient with acute abdominal pain.

Figure 9-18 CT angiography in a patient with recent gastrointestinal hemorrhage and normal colonoscopy.

A. Unenhanced CT image shows no radiodense material in the small bowel. **B.** Arterial phase of CT angiography shows active hemorrhage into an ileal loop. **C.** Conventional angiography confirms active bleeding from a small ileocolic arcade branch. **D.** Successful coil embolization of the ileocolic arcade branch.

thickened bowel loops with pneumatosis or altered enhancement (hyper- or hypoenhancement of the affected bowel) are signs of ischemia.

CTA has been shown to be a promising first-line modality for the diagnosis or exclusion of active GI hemorrhage (see Chapter 124). Mesenteric CTA allows accurate localization of the bleeding site, thus facilitating interventional planning.^{132,133} CTA may also provide information about causative factors, which in cases of lower GI bleeding can direct treatment by differentiating among colonic diverticulosis, angiodysplasia, neoplasms, and colitis. The diagnosis of active GI bleeding is made when hyperattenuating, extravasated contrast material is identified within the bowel lumen. An unenhanced scan is obtained immediately prior to CTA, and comparison with unenhanced images allows for the differentiation of active hemorrhage from any preexisting hyperattenuating areas that may

be present within the bowel lumen at the time of evaluation (Fig. 9-18). Coronal MIP reformatted images are useful for localizing the site of hemorrhage and are used in conjunction with the axial images to evaluate the proximal femoral vasculature when intravascular treatment is anticipated. Sagittal MIP reformats are useful for evaluating the rectum and origins of the celiac artery, SMA, and inferior mesenteric artery (IMA).¹³⁴

Summary

CTA is the byproduct of rapid advances in CT technology and has replaced diagnostic catheter angiography for many indications. Image acquisition and processing techniques can significantly affect diagnostic image quality. A thorough knowledge of the scanner hardware and contrast optimization methods is therefore essential.

Magnetic Resonance Angiography Pitfalls

Summary

Magnetic resonance angiography (MRA) is a noninvasive technique that has been used as an alternate to conventional angiography. Noncontrast and contrast-enhanced techniques have been used historically to evaluate the visceral vessels. The most widely used noncontrast methods include time-of-flight (TOF) and phase contrast (PC) MRA, which have been validated most extensively for renal MRA. Advances in MR technology have facilitated the implementation of three-dimensional, contrast-enhanced MRA (CE MRA), which significantly expanded the role of MR angiography in imaging of the abdomen. New developments have led to time-resolved, contrast-enhanced MRA, which in addition to providing static arterial or venous phase images, provides hemodynamic information by allowing multiple rapid 3D acquisitions during the first pass of contrast. In addition, blood pool gadolinium contrast allows for steady-state imaging of the aorta and visceral vessels. In this chapter, we briefly discuss the various MR angiographic techniques, with emphasis on contrast-enhanced MR angiography. Included are approaches to patient preparation, imaging protocols, and image postprocessing techniques used in the evaluation of visceral vasculature with MRA. Various clinical applications of MRA in the abdomen are illustrated through a discussion of specific disease entities.

Magnetic Resonance Angiography Techniques

NONENHANCED MAGNETIC RESONANCE ANGIOGRAPHY TECHNIQUES

Time-of-Flight

Time-of-flight (TOF) is the oldest MRA technique for the evaluation of vasculature. This technique exploits blood motion to visualize vascular structures directly without the use of intravenous contrast material. It is performed using a gradient-refocused sequence in which the stationary tissues are saturated, resulting in low background signal intensity. In contrast, the blood moving into the imaging volume is unsaturated, with full longitudinal magnetization, which when excited gives a bright signal compared to the stationary, saturated background tissues. There are limitations with the TOF technique. The most important is that TOF is time-consuming and requires patient cooperation. Long acquisition times limit its use during a breath-hold. In addition, this technique is susceptible to in-plane saturation and phase dispersion, preventing the application of TOF for routine evaluation of the visceral vasculature. TOF may still provide diagnostic images in the evaluation of large vessels such as the abdominal aorta, proximal portions of the celiac and superior mesenteric arteries, large venous structures such as the inferior vena cava (IVC), portal vein, superior mesenteric vein, and portosystemic collaterals.^{1,2} Diseased vessels or small arteries such as the proper hepatic, gastroduodenal, and branches of the superior mesenteric arteries are not well evaluated with this technique.^{1,4} The direction of portal venous blood flow can be assessed using the TOF technique by simply applying a saturation band over the portal vein. Contrast-enhanced and nonenhanced techniques have mainly replaced TOF imaging in the abdomen.

Phase Contrast Technique

The phase contrast (PC) technique uses phase shifts of the flowing protons in the vascular structures to create MRA images. Phase shifts of stationary tissues are compensated by using bipolar gradient. Two imaging acquisitions are performed, in which the first has a positive bipolar gradient and the second has a negative bipolar gradient. The data from these two acquisitions are subtracted in k space to eliminate phase shift induced by other sequence parameters. The net effect is an image of flowing spins. The amount of phase difference that remains after subtraction is proportional to the velocity of the moving spins. The flow sensitivity can be adjusted by setting the velocity encoding value, $V(\text{enc})$. $V(\text{enc})$ determines the highest and lowest detectable velocities encoded by a phase-contrast sequence. For example, $V(\text{enc}) = 100 \text{ cm/s}$ is ideal for a phase contrast MRA with a measurable range

of flow velocities of ± 100 cm/s. PC MRA allows for the functional assessment of mesenteric circulation and has been shown to be helpful for diagnosing mesenteric ischemia.⁵⁻⁷ The information from phase contrast measurements can be processed into magnitude (bright blood and anatomic) images or phase contrast (velocity) images. A major disadvantage of the PC technique is long acquisition times, requiring patient cooperation. Because the final image relies on subtraction, patient motion can be problematic. Turbulent flow distal to a region of stenosis may result in dephasing and signal loss, overestimating the stenosis grade. As a result of these many limitations, this technique is not typically used as a primary imaging tool for anatomic assessment of the visceral arteries or portal system.

Balanced Steady-State Free Precession

Balanced steady-state free precession (b-SSFP) is a rapid imaging technique that provides a very high signal-to-noise ratio with T2*/T1-weighted image contrast. The different T2*/T1 ratios of blood and surrounding tissue are beneficial for angiographic imaging.⁸ This technique is not flow-dependent, so venous structures demonstrate as bright a signal intensity as arterial structures. Clotted blood is low in signal intensity, depending on the clotting stage and composition of blood products. b-SSFP is best suited for morphologic imaging of the vessels. It allows a rough anatomic preview and visualization of background tissues, such as mural thrombus and vascular wall, which may not be optimally evaluated when using a contrast-enhanced MRA sequence alone. The drawback of this technique is the banding artifacts caused by magnetic field inhomogeneity. One solution to this problem is to use a very short repetition time (TR) to eliminate the artifacts from the regions of interest. Given the high signal-to-noise ratio of b-SSFP sequences, the bright signal intensity of fat can obscure anatomic structures. In such cases, effective fat suppression can be used to improve the image quality.

Other Techniques

Other procedures for noncontrast MRA are available, such as fresh blood imaging (FBI), NATIVE, and flow prep, which are based primarily on electrocardiogram (ECG), gated, fast spin-echo (FSE) sequences. This general technique relies on high signal during diastole and flow void during systole within the arteries secondary to differential velocity, which allows for images depicting only arteries or veins following subtraction. Although in principle this technique seems simple, it requires expertise on the part of the technologist and, because it relies on differential flow between systole and diastole, it does not perform well in the setting of severe disease. ECG-gated FSE sequences have been used primarily for peripheral vascular disease and aortic imaging, with little published experience in mesenteric imaging.

In addition to ECG-gated FSE sequences, another new technique is the quiescent-interval single-shot (QISS) sequence. This has demonstrated promise for peripheral vascular disease and also may be used to image the abdominal aorta and origins of the major visceral vessels.⁹ QISS is an ECG-gated slice selective 2D b-SSFP sequence that uses a tracking saturation pulse to eliminate venous signals. Images are acquired during the quiescent interval, coinciding with arterial inflow during systole. This new technique has yet to be thoroughly tested for application in mesenteric MRA.

CONTRAST-ENHANCED MAGNETIC RESONANCE ANGIOGRAPHY TECHNIQUES

CE MRA is the preferred MR technique for anatomic evaluation of the arterial and venous systems in the abdomen and pelvis. The image contrast is based on the differences in the T1 relaxation time of blood and the surrounding tissues. Gadolinium chelate is administered to significantly shorten the T1 relaxation time of blood and T1-weighted images are obtained, often with precontrast images obtained for reference and subtraction. Conventional 3D CE MRA techniques requiring bolus timing often provide good anatomic detail. Time-resolved techniques minimize the need for bolus timing and allow for the assessment of flow dynamics using high temporal resolution. Steady state high resolution imaging with blood pool agents can provide exquisite anatomic detail not previously attainable with extracellular agents.

Conventional Three-Dimensional Contrast-Enhanced Magnetic Resonance Angiography

CE MRA requires bolus timing with pre- and postcontrast 3D spoiled gradient-echo technique (3D SPGR/3D fast low-angle shot [FLASH]) using very short echo times (TEs) and repetition times (TRs) in combination with a relatively high excitation flip angle (25 to 40 degrees). No special preparation for the scan is required. Some studies indicate that a mesenteric MRA is better performed postprandially because there is increased splanchnic circulation.

After the patient is positioned supine on the table and centered for the midabdomen, the basic imaging protocol for mesenteric MRA generally starts with multiplane scout images of the abdomen. Coronal and axial true fast imaging with steady-state precession (FISP; balanced SSFP) images of the abdomen are acquired to provide anatomic assessment of the outer wall of the vessel and an additional set of localizers to position the subsequent test bolus and 3D MRA slab. A precontrast 3D MRA sequence is performed in the coronal plane for most applications; consider sagittal for celiac and superior mesenteric pathologies such as the median arcuate ligament or superior mesenteric artery (SMA) syndrome. To achieve the best image quality, use the shortest possible TR to shorten the acquisition time and a minimized TE to decrease the dephasing artifact and T2* effects. An appropriate flip angle is between 25 and 40 degrees. The thicknesses of slabs and sections vary, depending on the patient, to cover all the mesenteric vessels, including the hepatic arteries, superior mesenteric arteries, and branches. One should aim for a slice thickness of 1 to 1.5 mm after interpolation; however, for larger vessels, thicker slices may be sufficient and allow greater coverage.

If using the test bolus technique (see later), a timing bolus sequence (turbo FLASH sequences: acquisition speed = 1 image/s) of the abdominal aorta is performed in the sagittal plane using a test injection of gadolinium chelate (≈ 1 -2 mL, injected at a rate of 2-3 mL/s). If there is an aortic aneurysm, the estimated contrast arrival time should be timed at the distal part of the aneurysm. After the administration of contrast (0.1-0.2 mmol/kg, 2-3 mL/s) at an appropriate delay time (as calculated, or automatically triggered) followed by a saline flush solution of 15 to 20 mL at the same rate, two imaging sets are consecutively acquired postcontrast. The imaging time for each sequence should be less than 20 to 25 seconds to permit breath holding.

Contrast Material Dosage and Injection Rate. Appropriate timing of contrast material injection is critical in obtaining a good conventional 3D CE MRA, without significant venous contamination, for evaluation of the arterial system. The volume of contrast material and chasing saline solution, delivery rate, and scan delay time are important parameters that are to be adjusted to optimize image quality.

The arterial and venous enhancement pattern after the rapid contrast injection is shown in Figure 10-1.¹⁰ To achieve excellent image contrast and signal-to-noise ratio, the imaging sequence has to be timed so that the acquisition of the central portion of the k space (low-frequency data lines) corresponds with the plateau phase of maximum concentration of contrast material in the vessels of interest. If the central portion of the k space is filled prior to the peak of the contrast concentration, ringing or banding artifacts occur (Fig. 10-2). However, if images are acquired too, late venous contamination may obscure the arterial anatomy.

Injection rate and duration of injection also have a significant effect on the pattern of arterial enhancement. A faster injection rate leads to a sharper arterial peak and higher maximum arterial signal intensity, whereas a slower injection rate results in a lower and broader arterial peak and lower maximum arterial signal intensity.¹⁰ Contrary to the arterial enhancement pattern, the degree of venous enhancement does not vary substantially with the injection rate but primarily depends on the total dose of contrast material when using an extracellular contrast agent. Thus, a larger amount of contrast material leads to higher intravascular signal intensity when performing gadolinium-enhanced portography or venography.¹¹ The time to peak for venous enhancement is longer with a slower injection rate, and image acquisition should be delayed proportionally to obtain the best contrast enhancement in the venous structures.

As the technique of CE MRA imaging was first introduced, the images were acquired as non-breath-holds, with acquisition times of 3 to 5 minutes. Under these circumstances, the gadolinium chelate was preferably infused at a slow uniform

rate over the entire scan duration to prolong the window of preferential arterial to venous enhancement.¹² Now, high-speed gradient MR systems and improved sequences permit shorter acquisition times, typically shorter than 20 seconds, which allows data acquisition during the first pass of contrast material in a single breath-hold. Therefore a rapid bolus injection with an automatic MR-compatible power injector is preferred.

Many different approaches have been used to optimize the injection rate and dosage of contrast material for MR angiography. The dosage of extracellular contrast agents used for performing abdominal MR angiography usually varies from a single to a triple dose (0.1 to 0.3 mmol/kg). Although some studies have shown that a single dose of contrast is sufficient for diagnostic assessment of the aorta and its major branches with CE MRA,¹³⁻¹⁵ some investigators have reported that image quality, vessel delineation, and confidence in diagnosis improve with the use of a higher dose (double^{16,17} or triple dose¹⁸). However, double- and triple-dose methods have fallen out of favor because of the association of nephrogenic systemic fibrosis with gadolinium contrast agents.¹⁹ With regard to injection rate, a faster injection allows for a greater degree of preferential arterial to venous enhancement,¹⁰ and the interval between arterial and venous peaks tend to be longer with a higher injection rate.¹¹ Hence, venous contamination is diminished with a high-rate injection protocol. For mesenteric MRA, we use a single dose and inject at a rate of 2 to 3 mL/s, followed by a 20-mL normal saline flush at the same rate.

Bolus Timing Methods. Because the image quality of CE MRA depends primarily on the distribution and concentration of gadolinium during the acquisition of the center of the k space, proper timing is paramount to achieving a good MRA image, particularly when using fast imaging techniques. There are several ways to synchronize the arterial peak enhancement with the center of k space data acquisition.

Figure 10-1 Arterial and venous enhancement pattern after a bolus injection. For the best MR angiographic quality to be achieved without venous contamination, the data at the center of k space should be acquired during peak arterial enhancement, when there is still no contrast in the venous structures. The transit time is a delayed time after the bolus injection to when the data at center of k space is acquired.

Figure 10-2 Ringing or banding artifact. The image demonstrates ringing or banding artifacts (arrows), which occur when the central portion of k space is filled prior to the peak of the contrast concentration during rapid changing of the contrast concentration.

“Best Guess” Technique. This is the simplest timing method; it is performed by using an estimated contrast travel time from the injection site to the vascular structure of interest with sequential (linear) order of k space acquisition. The variation in contrast travel time depends on age, gender, injection site, injection rate, and other clinical parameters, such as cardiac output status and vascular anatomy. In general, the estimated contrast travel time from an antecubital vein to the abdominal aorta is approximately 15 to 18 seconds in a healthy young patient and 20 to 25 seconds in a healthy older patient. In patients with decreased cardiac output or a large aortic aneurysm, the estimated contrast travel time may vary widely, from 25 to 50 seconds.²⁰

Test Bolus Technique. This is a more precise timing method performed by injecting a small amount of contrast material (1 to 2 mL) followed by normal saline flush (10 to 20 mL) at the same injection rate as in the planned contrast-enhanced MRA study. The vascular structure of interest is imaged with a timing bolus acquisition (single-slice, fast 2D gradient-echo sequence) acquired at a rate of one image every second. Time to peak of contrast enhancement is determined visually or by drawing a region of interest over the vessel. When using a sequential (linear) order of k space acquisition in the 3D MRA sequence, the scan delay time is calculated as follows:

$$\begin{aligned} &\text{Imaging delay time or scan delay} \\ &= (\text{time to peak of contrast enhancement}) \\ &\quad + (\text{injection duration time}/2) \\ &\quad - (\text{time to center of k space}) \end{aligned}$$

If a centrally reordered k space acquisition sequence is used, the estimated scan delay is equal to the time to peak of contrast enhancement. This technique is robust and reliable and offers the advantage of making sure that the intravenous access is in good working condition before the main contrast bolus is injected. The drawback of this technique is that there is no guarantee that the imaging bolus will behave identically to the test bolus because of the differences in the total volume of injection, especially in the setting of poor cardiac function.

Automatic Triggering Technique. The automatic triggering technique (SmartPrep, GE Medical Systems, Waukesha, Wis.; ABLE, Siemens, Munich, Germany) is another technique to optimize the imaging delay time by automatically synchronizing the bolus arrival and image acquisition. In this technique, a tracker volume is placed over the desired vascular structure, typically at a level slightly proximal to the area of interest. The signal level of the tracker volume is obtained repeatedly and rapidly using a tracker sequence during the contrast injection. When the signal intensity reaches a threshold value (usually 2-3 standard deviations [SDs] or 15%-30% above the mean signal level), the 3D MRA sequence (3D SPGR sequence with centric reordering of k space) is triggered. In general, there is a 4- to 5-second delay between the detection of bolus and the start of 3D acquisition, which allows contrast to reach the peak and also gives enough time to suspend respiration. This method ensures that peak arterial and central k space data acquisition occur simultaneously.²¹ The disadvantages of this technique is that if the size of the tracker volume ($\approx 2 \times 2 \times 2.5$ cm) is larger than the arterial structure of interest and overlaps an

adjacent vascular structure, the bolus may be missed or inappropriately timed.

Magnetic Resonance Fluoroscopy. Magnetic resonance fluoroscopy (CARE bolus, Siemens) is a fluoroscopic triggering technique. Similar to the automatic triggering technique, the entire volume of contrast is injected. Using a fast 2D gradient-echo technique, rapid images are acquired in real time over the vessel of interest. As the contrast arrives in the vessel of interest, the 3D MRA sequence is triggered by the operator. The operator-triggered approach has some advantages. For example, in the evaluation of cases with asymmetric flow patterns, or in cases in which there is displacement of the monitoring plane because of patient motion, an experienced operator can adapt and initiate the triggering accordingly.²²

3D Time-Resolved, Contrast-Enhanced Magnetic Resonance Angiography

This allows for the rapid acquisition of volumetric data sets throughout the contrast bolus, which are then commonly displayed as sequential 3D subtracted maximum intensity projections. To make time-resolved MRA feasible, k space filling must occur in a few seconds or less. Bolus timing becomes less important because multiple phases of contrast are obtained and an arterial phase without venous contamination can be selected for review. Capturing multiple phases of contrast provides hemodynamic information similar to that obtained with digital subtraction angiography (DSA), adding new diagnostic capabilities not previously available with conventional 3D CE MRA.

In TR MRA, reduction in acquisition time is achieved through spatial and temporal undersampling of k space and subsequent Fourier interpolation and/or k space sharing. Multiple proprietary algorithms for k space filling have been developed to allow rapid volumetric data acquisition including TRICKS,²³ TREAT,²⁴ and TWIST.²⁵ In general, the periphery of k space (high spatial frequencies) is undersampled relative to the center of k space (low spatial frequencies), which maintains contrast resolution at the expense of spatial resolution. During sequence optimization, the primary trade-off is spatial versus temporal resolution. The background structures and vessel location do not change substantially during a contrast bolus, so undersampling, interpolating, or k space sharing can be used to maintain spatial resolution while reducing acquisition time. The high-contrast resolution volumetric datasets can then be displayed as maximum intensity projections and viewed in a sequential manner to evaluate hemodynamics. Temporal resolutions on the order of 2 to 4 seconds are optimal for capturing the hemodynamics of the mesenteric arterial system. Our current method uses k space sharing using TWIST, with an injection of the entire contrast bolus at 2 mL/s, followed by the acquisition of TR MRA over multiple measurements (usually spanning at least 2.5 minutes). Because this method relies on subtraction, it can be repeated at multiple stations or with split boluses, if needed. If a blood pool agent is used, pre- and post-contrast traditional 3D CE MRA sequences can be obtained in addition to TR MRA to provide higher resolution subtractions and maximum intensity projections (MIPs). The addition of fat-suppressed, T1-weighted, postcontrast sequences, such as a 2D FLASH (perhaps better suited for patients in whom bowel pathology is sought to limit motion blurring), or a 3D volumetric interpolated breath-hold examination (VIBE), may provide further anatomic detail of organs of interest.

Steady-State, High-Resolution, Contrast-Enhanced Magnetic Resonance Angiography

This is now feasible with the advent of blood pool gadolinium contrast agents. Gadofosveset trisodium (Ablavar) is a U.S. Food and Drug Administration (FDA)–approved MR imaging (MRI) blood pool contrast agent, specifically designed for MRA and approved for aortoiliac occlusive disease. After intravenous administration, Ablavar is 80% to 96% bound strongly but reversibly to serum albumin, resulting in a long intravascular elimination half-life. According to studies performed in rabbits and nonhuman primates, Ablavar is eliminated primarily through the renal system, and its intravascular half-time is approximately 2 to 3 hours.^{26,27} The binding of Ablavar to plasma proteins exhibits T1 relaxivity 6 to 10 times higher than that of extracellular gadolinium chelate compounds. This results in a strong persistent intravascular T1 shortening, giving an acquisition window of approximately 1 hour.²⁶ Thus, these blood pool contrast agents allow excellent vascular enhancement during dynamic and steady-state MRA.²⁸ Moreover, the longer imaging window facilitates the higher spatial resolution MR acquisition than would be possible with conventional extracellular gadolinium chelate contrast agents. This longer imaging window is also more forgiving in cases in which first-pass bolus timing is suboptimal.

Blood pool gadolinium agents may prove to be the ideal contrast agent for mesenteric MRA. This is because they function as well as extracellular agents in conventional 3D CE MRA and time-resolved MRA while providing improved opacification of venous structures for venography and allowing steady-state, high-resolution, 3D MRA. A sample mesenteric MRA protocol with a blood pool agent starts with a variable scout and then a partial half-Fourier acquisition single-shot turbo spin-echo (HASTE), with a coronal breath-hold and axial non-breath-hold. Then b-SSFP with fat saturation in the coronal and axial planes is obtained to provide background anatomic detail, including vessel walls and the presence of an intraluminal or intramural thrombus. Precontrast 2D FLASH with fat saturation in the axial plane with breath holding, and precontrast 3D spoiled gradient-echo images with breath holding in a coronal plane, with the posterior end of the slab positioned just behind the aorta, are obtained for subtraction with subsequent steady-state, high-resolution sequences. A test bolus or preferred bolus timing method is performed. Then a single dose of Ablavar is administered at 1 to 2 mL/s with an MR-compatible power injector. Two sequential 3D spoiled gradient-echo images with breath holding in a coronal plane are obtained postcontrast. 3D spoiled gradient-echo images with breath holding are then obtained in a sagittal plane (for celiac and superior mesenteric artery indications). Finally, 2D FLASH with fat saturation in an axial plane with breath holding is performed for high-resolution, steady-state postcontrast images. Postprocessing is performed to create subtraction images from pre- and postcontrast sequences, and 3D MIPs are reconstructed (Fig. 10-3A).²⁹

Image Postprocessing and Display

3D contrast-enhanced MRA produces a contiguous volume of image data so that it can be easily reformatted in any desired plane or reconstructed using various 3D reconstruction algorithms for better demonstration of targeted vessels.

Figure 10-3 Reconstruction techniques. A. Thick MIP reconstructions from subtracted steady-state CE MRA with Ablavar show normal venous and artery anatomy. **B.** Curved MPR of the CE MR portography in a different patient demonstrates an extensive thrombus in the portal vein (PV) and superior mesenteric vein (SMV).

SUBTRACTION

This is a simple postprocessing technique that allows elimination of the background tissue signal such as fat. To achieve subtraction, postcontrast images are subtracted from the pre-contrast images, resulting in a new subtracted dataset. The

subtracted dataset can be further postprocessed using any of the techniques described here.

MULTIPLANAR REFORMAT

Multipolar reformat (MPR) is the reconstruction of images in arbitrary orientations, such as orthogonal, oblique, or curved planes. This method allows the viewer to slide through a given volume in any plane in real time. These reformatted slices remain thin, eliminating overlapping structures and unfolding tortuous vessels. The reformatted images frequently provide better demonstration and additional diagnostic information, particularly in the evaluation of complex anatomic structures or areas that are traditionally difficult to evaluate on axial source images (Fig. 10-3B). For best MPR results, images should be as close to isotropic (the same size in all three voxel dimensions) as possible. This can be achieved easily during high-resolution, steady-state imaging with Ablavar. It should be noted, however, that the acquisition time of isotropic 3D datasets is long and generally cannot be acquired during a single breath-hold. The motion related to respiration does create significant blurring or distortion of the anterior half of the abdomen, but the aorta and proximal visceral vessels are generally well depicted because they are less susceptible to motion during respiration.

MAXIMUM INTENSITY PROJECTION

Maximum intensity projection (MIP) is the projection of pixels with highest intensity onto an arbitrarily oriented plane. MIP images have an aspect similar to that of conventional angiograms and are commonly used for angiographic display because vascular signal is much greater than background signal. The image data can be reconstructed in a full-volumetric MIP (Figs. 10-4 to 10-6) or subvolumetric MIP (Figs. 10-7 and 10-8), in which only a small portion of the slab is reconstructed. The thickness of the slab and desired viewing plane can be adjusted. A drawback of MIP images is the lack of depth information, so that objects lying in the same projection plane of high-intensity structures cannot be visualized.³⁰ For example, stationary tissues that have greater signal intensity than vascular structures, such as fat, hemorrhage, or metallic susceptibility artifact, can lead to mapping of these nonvascular structures to the projection image and cause a discontinuity in the vessel signal, potentially mimicking stenosis or occlusion.³¹ On the other hand, eccentrically located stenoses may remain undetected.³² Careful evaluations with multiple angle projections, as well as use of the subvolumetric MIP reconstruction technique, can help minimize the chance of diagnostic errors incurred by full-volumetric MIP images. Given the potential pitfalls, MIP images should be used as a road map, whereas source images and MPR are used preferably for definitive diagnosis.^{17,30,33}

SHADED SURFACE DISPLAY

Shaded surface display (SSD) is the three-dimensional display of a surface from a series of contiguous slices using variable threshold settings. The 3D objects can be rotated and tilted in real time. The unwanted overlying structures can be easily eliminated using volume segmentation and confinement. Because SSD allows 3D visualization, it provides a clear 3D understanding of the patient's anatomy for improved surgical and treatment planning (Figs. 10-9 and 10-10).

Figure 10-4 Visceral artery aneurysms. **A.** Full volumetric coronal MIP image with contrast-enhanced abdominal MRA in an 18-year-old woman who presented with a duodenal hemorrhage reveals multiple aneurysmal dilation of the superior mesenteric artery. **B.** Sagittal thick MIP subtraction images from MRA with Ablavar demonstrate an isolated celiac aneurysm in a patient with a history of aortic dissection. **C.** Axial thin MIP images with abdominal MRA demonstrate fusiform dilation of the celiac trunk and hepatic artery in a different patient.

VOLUME RENDERING

Volume rendering (VR) is another 3D visualization tool. In contrast to SSD, not only is the surface displayed, but VR also allows the entire range of signal intensity within a volume data set to be illustrated. Objects with high signal intensity are opaque, and objects with low signal intensity are transparent. Thus, tissue differentiation is more feasible and the internal structures that would normally be hidden when using SSD can be demonstrated using VR. The display parameters, including window width, window level, opacity, and brightness, can be manipulated to obtain the optimal visualization of the areas of interest.

Clinical Applications of Abdominal Magnetic Resonance Angiography

CHRONIC MESENTERIC ISCHEMIA

Chronic mesenteric ischemia (CMI) is a gradual occlusive process, mostly caused by atherosclerotic changes of the

Figure 10-6 Inferior vena cava and iliac vein thrombosis. **A.** Coronal full volumetric MIP reconstruction of contrast-enhanced MR venography demonstrates no opacification of the inferior vena cava. **B.** Coronal reformatting reveals an extensive thrombus within the inferior vena cava and left iliac vein (arrows).

Figure 10-7 Celiac artery dissection. **A.** Axial spoiled gradient-echo postgadolinium MRI image demonstrates a dissecting flap within the celiac trunk. **B.** In a different patient, coronal thick MIP reconstruction from subtraction abdominal MRA with Ablavar demonstrates a celiac artery aneurysm with isolated celiac dissection.

Figure 10-8 Segmental arterial mediolysis. Transaxial thin MIP postgadolinium spoiled gradient-echo images in this 51-year-old man demonstrated multifocal narrowing and beaded irregularity of the celiac axis (**A**), with aneurysmal dilation and dissection of the superior mesenteric artery (**B**).

Figure 10-9 Median arcuate ligament syndrome. Sagittal MIP reconstruction of abdominal MRA (**A**) and surface-rendered sagittal reconstructions (**B**) in a 29-year-old man demonstrate external superior indentation with narrowing of the celiac trunk (anterior arrow) with poststenotic dilation caused by median arcuate ligament (posterior arrow) compression. **C.** Sagittal MIP reconstruction after median arcuate ligament release and reconstruction shows resolution of the celiac stenosis (arrow).

Figure 10-10 Portal hypertension with spontaneous splenorenal shunt. Full volumetric axial MIP image with 3D contrast-enhanced MR portography reveals a large portosystemic collateral pathway from the splenic to left renal vein, secondary to portal hypertension.

splanchnic arteries.^{34,35} The bowel remains viable but its blood supply is inadequate to support its metabolic and functional demands. The classic symptoms of CMI include postprandial abdominal pain, weight loss, and food avoidance.^{36,37} The diagnosis of CMI is made by a combination of appropriate clinical symptoms and the demonstration of significant stenosis in two or three of the three main mesenteric vessels.³⁷ Contrast-enhanced 3D MRA provides anatomic information similar to that of conventional angiography (Figs. 10-11 and 10-12). Its effectiveness in evaluation of mesenteric circulation has been well documented.³⁸⁻⁴⁰ A 100% sensitivity of CE 3D MRA to detect stenoses of the celiac artery (CA) and SMA was reported

in a prospective study of 125 patients.⁴⁰ Meaney and colleagues³⁸ reported a sensitivity of 100% and specificity of 87% in the overall detection of visceral artery stenosis. Unfortunately, its accuracy is lower in evaluation of the small peripheral branches. Shirkhoda and associates³⁹ found that correct assessment was obtained in 75% of first-order branching, 60% of second-order branching, and 50% of third-order branching vessels of the SMA.

Mesenteric circulation is often supported by extensive arterial collateral vessels that develop over time, because the occlusive process is gradual in onset. Thus, the significant stenosis of two or three of the major mesenteric vessels can be seen in patients who are completely asymptomatic.^{34,36} Many investigators⁵⁻⁷ have proposed MR flow quantification using cine phase contrast MRI for the diagnosis of CMI. It allows for the functional evaluation and quantification of mesenteric vascular flow, which can be measured separately in the main mesenteric arteries^{5,6} (CA, SMA, and inferior mesenteric artery [IMA]) or superior mesenteric vein.^{6,7} In healthy volunteers, there is an expected postprandial increase in mesenteric blood flow, whereas there is diminished postprandial flow augmentation in the diseased patient. The greatest difference in flow rates between normal and diseased patients is achieved when measurements are made 30 minutes postprandial.⁷

MEDIAN ARCUATE LIGAMENT SYNDROME

Median arcuate ligament syndrome (see Fig. 10-9) results from compression of the celiac artery by the median arcuate ligament and is a well-documented anatomic variant, seen in 12.5% to 49.7% of patients^{41,42} and resulting in intestinal angina in some cases.⁴³ The clinical symptoms include postprandial pain and an abdominal bruit on physical examination. The compression of the celiac axis varies with respiration. During inspiration, the aorta and celiac axis move downward with the abdominal viscera, whereas in expiration, the vessels move cephalad, resulting in maximal external compression. As a result, the MRA images obtained during end-expiration may accentuate the

Figure 10-11 Chronic mesenteric ischemia. Coronal (A) and sagittal (B) MIP reconstruction with abdominal MRA demonstrates atherosclerotic changes of the abdominal aorta and segmental occlusion at the origin of the superior mesenteric artery (arrow) in a 65-year-old man. Note that the distal part of the superior mesenteric artery is revascularized by collaterals arising from the left marginal artery (arrowhead).

Figure 10-12 Acute celiac and superior mesenteric artery bypass graft occlusion. A. Sagittal MIP reconstructions with abdominal MRA in a 67-year-old man demonstrate abrupt termination of the celiac bypass graft without flow, either in the hepatic artery or superior mesenteric bypass graft. B. Postcontrast spoiled gradient-echo image demonstrates occlusion of the SMA bypass graft and infarction of the left lobe of the liver.

celiac artery compression and can give rise to a potential interpretation pitfall. Thus, when median arcuate ligament syndrome is suspected on the basis of end-expiratory imaging, findings should be correlated with the clinical history and physical examination or confirmed with end-inspiration imaging. In general, MRA should be performed at end-inspiration in patients suspected of having intestinal ischemia.⁴⁴

SPLANCHNIC ARTERY DISSECTION

Splanchnic artery dissection (including the celiac axis, hepatic artery, SMA, and splenic artery) (see Fig. 10-7) can be

spontaneous and isolated,⁴⁵⁻⁴⁷ but most occur secondary to dissection of the aorta. The extension of aortic dissection into abdominal branch vessels can lead to visceral organ ischemia. There are two types of visceral artery involvement. More commonly, the intimal flap extends into the visceral artery, separating the vessel into two lumens, one of which is supplied by the true lumen and the other by the false lumen. In these cases, thrombosis of the false lumen or compression of the true lumen can lead to luminal compromise, resulting in ischemia and infarction. Less often, the branching arteries may be supplied exclusively by the false lumen. In these cases, compromise of vascular supply to the internal organs occurs less frequently.⁴⁸

VISCERAL ARTERY ANEURYSMS

Visceral artery aneurysms (see Fig. 10-4) are uncommon; nevertheless, they hold a high clinical significance because of their potential for rupture, resulting in life-threatening hemorrhage. Formerly, the most commonly affected vessel was believed to be the splenic artery.⁴⁹ However, an increasing incidence of hepatic artery pseudoaneurysms has recently been reported because of the increased use of percutaneous diagnostic and therapeutic procedures.⁵⁰ The other commonly affected vessels, in decreasing order, include the superior mesenteric, celiac, gastric, gastropiploic, ileocolic, and pancreatoduodenal arteries.^{50,51} When an aneurysm is thrombosed, it can be overlooked on MRA MIP images. This potential pitfall can be avoided by reviewing the MRA source images.

SEGMENTAL ARTERIAL MEDIOLYSIS

Segmental arterial mediolysis (SAM), initially described as segmental mediolytic arteritis,^{52,53} occurs because of mediolysis in the muscular arteries of the abdomen, with subsequent separation of the muscular layer from the adventitia. Radiologically, it manifests as arterial dilation, a single aneurysm or multiple aneurysms creating a string of beads, dissecting hematomas, arterial stenosis, and arterial occlusion (see Fig. 10-8), which occur segmentally in single or grouped abdominal arteries. Diagnosis is often made after a clinical presentation of intra-abdominal hemorrhage from an aneurysm rupture or as an incidental finding. It has been proposed that SAM is a precursor to fibromuscular dysplasia⁵⁵ because of its pattern of distribution, but there is no definitive evidence linking the two entities.⁵⁴

EVALUATION OF HEPATIC VASCULATURE

This is frequently requested for pre- and post-transplantation assessment and to evaluate for postprocedural complications (Fig. 10-13; see Fig. 10-10). Although basic anatomic variants and thrombus can be assessed with standard postcontrast spoiled gradient-echo imaging, MRA of the hepatic vasculature, including arteries, portal vein, and hepatic veins, is feasible and may provide additional information when unexpected pathology is encountered or for living donor pre-explantation evaluation. For this indication, the recipient and donor should be preoperatively evaluated for anatomic variations that might alter the surgical approach or exclude patients for whom surgery is not feasible. For example, in recipients, the small-caliber native hepatic artery increases the surgical complexity of creating a patent and durable anastomosis between the donor and recipient artery.⁵⁶ A stenosed celiac artery might precipitate post-transplantation ischemia and require an arterial bypass. A replaced or accessory left hepatic artery arising from a left gastric artery has to be ligated at its origin during removal of the native liver to prevent bleeding. CE MRA is also an excellent method for preoperative portal vein assessment (MR portography), including evaluation of portal hypertension, portosystemic shunts, portal vein thrombosis, and portal vein invasion by tumors.

For evaluation of living related liver donors, MRI can be used as the sole imaging technique for preoperative evaluation. Other than detection of liver lesions and biliary anomalies, MRA of the hepatic vasculature is needed to determine the patency and anatomy of the hepatic arteries, portal veins, and hepatic veins. Although not all vascular variants are surgically significant, there are some features that one should take into consideration

Figure 10-13 Budd Chiari syndrome and portosystemic shunts. A. Coronal MIP reconstructions from subtracted steady-state MRA with Ablavar demonstrate lack of visualization of the hepatic veins with a large superior mesenteric vein to gonadal vein varix in the setting of Budd Chiari syndrome. **B.** Axial 2D postgadolinium spoiled gradient-echo steady-state image through the liver shows absence of normal hepatic veins.

prior to surgery, especially in patients at risk for liver failure. For example, the origin and location of the artery supplying segment 4 (middle hepatic artery) of the liver should be identified preoperatively because it should be left intact in the donor to prevent parenchymal damage to the medial segment of the liver. Thus, if the middle hepatic artery arises from the right hepatic artery, this variant may not be important for an adult to child liver donor because only the lateral segment of the left lobe would be taken. On the other hand, in an adult to adult liver donor, for whom the right lobe of the liver would be taken out, the resection line typically crosses the arterial supply of segment 4, leading to ischemic damage of the residual liver. Similarly, for left lobe donors, the replaced left hepatic artery arising from the left gastric artery should be identified preoperatively. For portal venous variations, such as the trifurcation of portal veins into right anterior, right posterior, and left portal venous branches, is a surgically significant finding that has to be evaluated preoperatively before contemplating surgical resection. Hepatic venous anatomic variants such as accessory hepatic veins and the anatomy of the hepatic venous confluence should be evaluated preoperatively because accidental transection can result in bleeding and atrophy of the supplied hepatic segment.⁵⁷

MAGNETIC RESONANCE PORTOGRAPHY

This was formerly performed with nonenhanced MRA using TOF and phase contrast techniques (see Fig. 10-6). These techniques are primarily limited by long data acquisition time, motion, flow artifacts, and in-plane saturation effects. Alternatively, CE MR portography is excellent for the evaluation of the portal venous system and various pathologic conditions, such as portosystemic shunt, portal vein thrombosis, cavernous transformation, and tumor invasion of the portal vein (Fig. 10-14).⁵⁸ The principle of contrast-enhanced MR portography

Figure 10-14 Normal contrast-enhanced portal venography. Coronal subvolumetric MIP reconstruction of the 3D contrast-enhanced MR portography scan demonstrates normal opacification of the portal, splenic, and superior mesenteric veins.

is to image a high concentration of contrast material circulating in the portal venous system. Boeve and co-workers⁵⁹ found that optimal portal venous enhancement is mostly achieved at 30 seconds after maximum arterial enhancement. Practically, after gadolinium injection, three or four 3D MRA datasets are obtained. The first dataset acquired after contrast administration is usually an arterial phase, which can be used as a mask for image subtraction. Contrast-enhanced 3D MR portograms can then be created by reconstructing images of the portal phase (usually the second or third 3D dataset acquired after contrast administration) with MIP. A subtraction technique can be used to eliminate arterial enhancement when such enhancement conceals the portal venous anatomy.⁶⁰

The major limitation of CE MR portography is its inability to provide hemodynamic data regarding flow direction in the portal venous system. Portal venous flow direction can be assessed by using phase contrast MRA or 2D gradient-echo TOF sequences with a saturation band placed across the proximal aspect of the portal vein, with another saturation band placed transversely above the hepatic dome to eliminate signal within the hepatic artery. In normal hepatopetal flow, the distal portal vein beyond the first saturation band should lose the signal intensity. Bright signal intensity beyond the first saturation band indicates an abnormal hepatofugal flow.⁶¹

DISEASES OF THE INFERIOR VENA CAVA

Diseases of the IVC (see Fig. 10-6) and iliac veins can be evaluated with the 2D TOF technique with a superior traveling saturation band to suppress the arterial signal. Many prior studies⁶²⁻⁶⁵ have shown high accuracy and high sensitivity of TOF MRA for detecting thrombosis in the abdominal and pelvic vessels. 3D CE MR venography (MRV) is also a sensitive technique for evaluation of the IVC. The best delineation of venous structures is obtained by using a blood pool contrast agent and imaging during the steady state. This technique allows for higher spatial resolution images to evaluate for venous stenosis, webs, and neoplasms. Also, 3D data can be reconstructed into any desired plane to achieve the best anatomic delineation, especially when acquired as a 3D isotropic dataset.

Magnetic Resonance Angiography Pitfalls

MRA has several potential pitfalls. Some diagnostic problems are caused by improper scan technique. For example, inappropriate positioning of the imaging volume may produce false-positive occlusion of the vessels by elimination of structures from the imaging volume. Banding or ringing artifacts result from suboptimal timing when the center of k space data is acquired before the peak of contrast enhancement. This can result in a dark signal with the vessel and can mimic dissection or occlusion of the vessel. Some MRA pitfalls result from subtraction and reconstruction techniques. For example, the aneurysm with a mural thrombus may be misinterpreted as a normal vessel because MIP images only depict the opacified lumen. Also, MIP may cause overestimation or underestimation of stenosis because of partial volume effects or poor spatial resolution. Because MIP is generated by projecting only the pixel with the highest attenuation along a ray projected through

the dataset, the signal intensity within the volume-averaged pixels may simply be below the MIP threshold and may be erroneously excluded from the final image, resulting in an overestimation of the stenosis. Conversely, if the stenotic segment extends equally into two pixels, the signal intensity would be averaged over the two pixels, and each pixel would appear in the MIP image as part of the lumen, resulting in underestimation of the stenosis.^{66,67} Metallic artifacts from vascular stents and surgical clips may obscure the adjacent vascular structures and simulate stenosis. However, most MRA interpretation pitfalls can be avoided by cautiously reviewing the source images.

Summary

Evaluation of mesenteric vessel patency and flow dynamics can be achieved with high spatial and contrast resolution images using CE MRA techniques. In particular, time-resolved methods allow for the evaluation of hemodynamics similar to that seen on DSA. With the use of blood pool contrast, steady-state imaging for venous pathology and for high-resolution isotropic dataset acquisition can be carried out. Thus, MRA provides a noninvasive and nonionizing radiation method for the evaluation of the mesenteric vessels and, when performed in combination with anatomic sequences, also provides end-organ information.

Retroperitoneum and Abdominal Wall

Pelvis

From the 1970s to 1990s, the abdominal radiograph traditionally served as the initial radiologic means of evaluating patients with suspected abdominal pathology. During the past two decades, however, computed tomography (CT) has become the major imaging procedure in patients with suspected acute abdominal pathology.¹⁻³ When abdominal radiography was performed as a screening test, the diagnostic yield of this examination was low and most abnormalities that were detected were nonspecific.⁴⁻⁶ In a review of 1780 screening abdominal radiographs, important abnormalities were found in only 10% of cases.⁵ No clinically significant disease would have been missed if abdominal radiographs had been obtained only in patients with a strong clinical suspicion of disease and/or moderate to severe abdominal symptoms. Abdominal radiographs have the greatest value in patients in whom bowel obstruction or perforation, urinary calculi, or bowel ischemia is suggested on clinical grounds.^{2,3,7-9} In patients with mild or nonspecific symptoms, however, abdominal radiographs have a low diagnostic yield. The major value of a normal abdominal series is the exclusion of bowel obstruction or free air secondary to bowel perforation.⁷⁻⁹ Despite the increasing use of CT and the declining role of abdominal radiography, this examination is still performed in many patients, especially those who have undergone recent surgery and those who have some form of catheter, tube, or drain in the abdomen. Emergency department physicians may also order abdominal radiographs in patients with a low clinical suspicion of disease to ensure that a major abdominal disorder is not overlooked and to calm a concerned patient.

Technique

STANDARD PROJECTIONS

An anteroposterior radiograph taken with the patient in a supine position is the most common plain film examination of the abdomen (Fig. 11-1). Whether one uses conventional film or digital techniques, the patient should be positioned

comfortably on his or her back, without rotation of the pelvis. Maximal relaxation of the abdominal musculature is important in reducing artifact caused by motion; this is facilitated by supporting and slightly flexing the patient's knees. The film or field of view for digital imaging should be positioned with its lower edge at the symphysis pubis and the x-ray beam centered at the iliac crest. Both the lung bases and symphysis pubis should be included on the radiograph. The exposure is made during expiration and should begin 1 to 2 seconds after respiration is suspended.¹⁰

Delineation of intra-abdominal soft tissues on abdominal radiographs depends on the inherent contrast provided by soft tissues, fat, and intraluminal gas. Subject contrast on the radiograph is caused by differential attenuation of the x-ray beam in the patient.¹¹ Most abdominal radiographs are taken using routine equipment exposed at a low kilovoltage (60-75 kV), depending on the size of the patient.¹⁰ A short exposure time is desirable to avoid motion unsharpness. Also, an increase in peak kilovoltage increases scattered radiation, which degrades soft tissue contrast. Thus, the lowest possible peak kilovoltage that can penetrate the patient and has an acceptable exposure time should be used. With conventional films, a reciprocating (Potter-Bucky) grid and careful collimation are used to reduce scatter.¹⁰ In males with reproductive potential, gonadal shielding should be used if the gonads lie within 5 cm of the primary beam and if such shielding does not compromise the clinical objectives of the examination.

Portable abdominal radiographs may be obtained in hospitalized, extremely ill patients; however, these radiographs are usually of lower quality than standard abdominal radiographs obtained in the radiology department. Such patients are usually too ill to breath-hold, and most portable x-ray units have fixed milliamperage settings, which may necessitate using techniques of higher peak kilovoltage, resulting in reduced contrast. In addition, a stationary grid, rather than a Potter-Bucky grid, must be used to control scatter, and when these grids are poorly positioned, the image may be degraded secondary to grid cutoff. Whenever possible, abdominal radiographs should therefore be obtained using standard x-ray equipment in the radiology department.

SUPPLEMENTAL PROJECTIONS

In addition to the standard anteroposterior supine view, other projections may help in specific clinical situations and are frequently used as part of a routine abdominal series. In patients with abdominal pain, upright posteroanterior abdominal or chest radiographs may be useful to facilitate detection of small amounts of free intraperitoneal air, small bowel obstruction, and unsuspected thoracic disease that is causing abdominal pain (Fig. 11-2; see Fig. 11-1B).

Figure 11-1 Normal supine and upright abdominal radiographs.

A. Supine abdominal radiograph shows a normal bowel gas pattern with gas in the stomach (large white arrow), small bowel (small white arrow), colon (large white arrowheads), and rectum (black arrowhead). The hepatic angle (curved white arrow) is outlined by extraperitoneal fat, and the posteromedial surface of the right lobe of the liver is outlined by perirenal fat (small white arrowheads). The left psoas muscle (black arrow) is also seen. **B.** Upright abdominal radiograph shows a normal air-fluid level in the stomach (large white arrow). Note the hepatic angle (small white arrow), posteromedial surface of the right lobe of the liver (arrowheads), left psoas muscle (large black arrows), and splenic tip (small black arrow). **C.** Axial CT scan of the upper abdomen shows fat outlining the wall of the stomach (St) and spleen (S). **D.** Another more caudad axial CT scan shows the posteromedial surface of the right lobe of the liver outlined by perirenal fat (arrows).

An upright abdominal radiograph is often ordered on a routine basis, but some authors believe that it does not contribute significant information in many patients. Mirvis and colleagues reviewed the emergency department radiographs of 252 patients, which included supine and upright abdominal radiographs and upright chest radiographs.⁶ The upright abdominal radiographs did not contribute to the treatment of any patients with acute abdominal conditions in their series. The authors concluded that this view could be omitted to reduce the time and cost of the examination without sacrificing important diagnostic information. However, upright abdominal radiographs may be helpful in patients with suspected bowel obstruction who have a gasless abdomen on supine radiographs to assess the appearance of gas and fluid in the small bowel further (see Fig. 11-2A and B). Alternatively, this information could be obtained on abdominal radiographs taken with the patient in the lateral decubitus position. For extremely ill patients who cannot stand easily, a lateral decubitus view may be more helpful than a suboptimal upright radiograph.

Miller and Nelson showed that when a perforated viscus is suspected on clinical grounds, a specific sequence of exposures is most likely to demonstrate extraluminal gas.¹² They recommended that the patient be placed in the left side down position for at least 10 minutes before a left lateral decubitus view is obtained. This allows gas to rise and accumulate over the right margin of the liver and, occasionally, beneath the iliac crest. If the patient is unable to stand, an abdominal radiograph should

be obtained with the patient in the left lateral decubitus position with a horizontal beam, using a short exposure technique. This results in underpenetration of the abdominal viscera but good visualization of extra-alimentary gas between the non-dependent lateral abdominal wall and liver (Fig. 11-3). If the patient is able to stand, the table is tilted upright and an upright posteroanterior chest radiograph is obtained. In one study, lateral chest radiographs were found to be superior to frontal radiographs in detecting subtle pneumoperitoneum.¹³ Radiographs of the abdomen in upright and supine positions are also obtained to complete the so-called perforation series (see Fig. 11-2C and D).¹⁴ Even tiny amounts of free air can be detected with use of the proper technique (see Fig. 11-2E). Some authors have reported that upright posteroanterior chest radiographs are more sensitive for detecting pneumoperitoneum than upright abdominal radiographs.¹² This difference in sensitivity probably occurs because the x-ray beam is centered at the iliac crest on abdominal radiographs, so that it penetrates air beneath the diaphragm obliquely rather than tangentially, making small gas collections more difficult to detect. The higher exposure techniques required to penetrate the abdomen also result in excessive penetration at the lung interface, sometimes obscuring small collections of free intraperitoneal air. Nevertheless, most experts believe that upright and supine abdominal radiographs are a useful part of the abdominal series for detecting intra-abdominal disease in these patients.^{14,15}

Figure 11-2 Value of upright abdominal radiograph in patients with small bowel obstruction or intestinal perforation. **A.** Supine abdominal radiograph shows a relatively gasless abdomen in a patient with signs and symptoms of intestinal obstruction. **B.** Upright radiograph shows multiple tiny air-fluid levels (arrows) caused by fluid-filled loops of dilated small bowel with trapping of air superiorly in these loops (producing the string of pearls sign). The patient was found at surgery to have a closed loop small bowel obstruction due to adhesions. **C.** Supine abdominal radiograph in another patient with abdominal pain shows no evidence of pneumoperitoneum. Note residual contrast material in the colon from a prior study. **D.** Upright abdominal radiograph in the same patient as in **C** shows a large amount of free intraperitoneal air (arrows) beneath both hemidiaphragms. **E.** Upright radiograph in another patient shows a tiny amount of free air (arrows) between the liver and right hemidiaphragm.

Figure 11-3 Value of left lateral decubitus radiograph of the abdomen in a patient with pneumoperitoneum.
A. Coned-down view of the right upper quadrant from a supine abdominal radiograph shows a vague radiolucency in the right lateral portion of the abdomen (arrow) but no definite free intraperitoneal air. **B.** Coned-down view of the right upper quadrant from a left lateral decubitus radiograph shows obvious free intraperitoneal air (arrows) between the liver and right lateral abdominal wall.

Additional projections such as prone, oblique, lateral, or coned views may be helpful in some clinical situations for better defining and localizing mass lesions, calcifications, or hernias. When distal colonic obstruction is suspected, prone abdominal radiographs are more helpful than supine radiographs because colonic gas occupies the more anterior transverse and sigmoid segments of the colon with the patient in the supine position (Fig. 11-4A, C, and D). As a result, a distal colonic obstruction may be difficult to distinguish from an ileus or pseudo-obstruction on supine and upright views of the abdomen. In this situation, a prone radiograph (Fig. 11-4B) or right lateral decubitus radiograph (Fig. 11-4E) may be useful because abdominal radiographs in these positions allow gas to fill the rectosigmoid colon if no mechanical obstruction is present.¹⁶

Normal Anatomy

Abdominal soft tissue planes and visceral surfaces are visible on abdominal radiographs because of the natural contrast created by surrounding fat. The best visualized interfaces are those that are smoothly margined and oriented in a sagittal or transverse plane tangential to the incident x-ray beam. Familiarity with the location of abdominal organs and the most commonly visualized tissue planes is helpful for identifying normal anatomic structures and recognizing and localizing pathologic processes.

PERITONEAL CAVITY

Liver

In the normal adult, the liver occupies the right upper quadrant of the abdomen. It measures 20 to 22 cm in its greatest transverse dimension and 15 to 17 cm in its greatest vertical

dimension near its right lateral border.¹⁷ There is considerable variation in the normal shape of the liver.¹⁸ With its most cephalad portion lying just beneath the dome of the right hemidiaphragm, the superior aspect of the liver is commonly S-shaped or concave. The inferior edge is usually triangular, with its apex directed caudad toward the right lower quadrant. Between 4% and 14% of the population has a prominent inferior extension of the right lower lobe, also known as *Riedel's lobe*. This lobe usually extends caudally below the iliac crest and does not by itself indicate hepatomegaly.

Although intraperitoneal fat is not always present around the liver, the right inferior edge of the liver (hepatic angle) is often visible on abdominal radiographs because it indents the extra-peritoneal fat in the parietal peritoneum (Fig. 11-5; see Fig. 11-1).¹⁸ This fat consists of posterior pararenal fat laterally and perirenal fat medially. The perirenal fat may outline not only the medial aspect of the hepatic angle but also the more cephalad portion of the posteromedial surface of the right lobe of the liver (see Fig. 11-1A). The hepatic angle may be obscured by effusions or blood that infiltrate the retroperitoneal fat or by ascites that displaces the liver edge away from the adjacent fat (Fig. 11-6).¹⁹ The posterior edge of the liver is visible on abdominal radiographs (see Fig. 11-1), whereas the anterior and left lateral margins of the liver are not. Because it is the anterior margin of an enlarged liver that is palpated on physical examination, a discrepancy may arise between clinical and radiographic measurements of the liver. On abdominal radiographs, hepatomegaly may be diagnosed by elevation of the right hemidiaphragm, visualization of the entire liver (not just a Riedel's lobe) extending into the lower abdomen, inferior displacement of the hepatic flexure of the colon, and lateral displacement of the lesser curvature of the stomach by an enlarged left lobe of the liver.²⁰

Figure 11-4 Value of prone and right lateral decubitus abdominal radiographs in patients with suspected colonic obstruction. **A.** Supine abdominal radiograph shows dilated colon to the level of the sigmoid with some stool but a paucity of gas in the rectum. Note residual barium in sigmoid diverticula. **B.** Prone abdominal radiograph in the same patient as in **A** shows gas in the sigmoid colon (small arrows) and rectum (large arrow), confirming that the patient does not have a distal colonic obstruction. **C, D.** Supine abdominal radiographs in another patient with abdominal distention show marked colonic dilation, with a paucity of gas in the rectum. **E.** Right lateral decubitus radiograph in the same patient as in **C** and **D** shows gas in the rectum (arrow), confirming that the patient does not have a distal colonic obstruction.

Gallbladder

The gallbladder occupies a shallow fossa on the inferior surface of the liver between the right and left lobes and is not usually visualized on abdominal radiographs.¹⁷ The gallbladder lies superior and lateral to the duodenal bulb and gastric antrum and superior to the proximal transverse colon. Occasionally, the fundus of the gallbladder may be visualized in normal patients if it indents the surrounding fat (Fig. 11-7; see Fig. 11-5A). Only about 15% of gallstones are sufficiently calcified to be seen on abdominal radiographs, so the abdominal series is a poor screening study for gallbladder disease.

Spleen

The spleen occupies the left upper quadrant of the peritoneal cavity beneath the left tenth rib and hemidiaphragm, posterolateral to the gastric fundus (see Figs. 11-1B and 11-5).²¹ The

normal adult spleen measures 12 cm in length and 7 cm in width.²⁰ The lower edge of its inferolateral surface often indents extraperitoneal fat, and the lower medial aspect is adjacent to the left kidney and may be outlined by perirenal fat, enabling it to be visualized on abdominal radiographs (see Figs. 11-1B and C and 11-5). The bulk of the spleen, however, extends medially behind the stomach, where it is not visible on abdominal radiographs, so splenomegaly cannot always be diagnosed on these radiographs. Nevertheless, an enlarged spleen should be suspected when abdominal radiographs show elevation of the left hemidiaphragm, medial displacement of the gastric air bubble, or the splenic tip below the left costal margin.²⁰

The most inferior surface of the spleen abuts the phrenicocolic ligament, a thick peritoneal fold that marks the anatomic splenic flexure of the colon. The left lateral pleural recess may extend inferiorly along the lateral margin of the spleen to the splenic tip.²¹

Figure 11-5 Gallbladder, liver, spleen, and stomach. **A.** Supine abdominal radiograph shows the gallbladder (small black arrows), hepatic angle (large black arrowhead), splenic tip (white arrowhead), and stomach (large black and white arrows). Note the partially visualized right kidney (small black arrowheads). **B.** Coronal CT scan of the abdomen shows the hepatic angle (large arrow) outlined by perirenal fat, splenic tip (small arrow), psoas muscles (arrowheads), and kidneys. L, liver; K, kidney; Sp, spleen; St, stomach.

Figure 11-6 Intraperitoneal fluid (hemorrhage) in paracolic gutters. **A.** Supine abdominal radiograph in a patient with a traumatic liver laceration shows a large amount of fluid in both paracolic gutters (arrows) displacing bowel medially from the flank stripes. Also note loss of the hepatic angle normally outlined by extraperitoneal fat. The bleeding was controlled by embolization of the liver (note the radiopaque coil overlying the liver). **B.** Axial CT scan of the abdomen confirms the presence of ascitic fluid displacing adjacent bowel (arrows) from the paracolic gutters.

Stomach

The stomach usually contains air and fluid, so it can be recognized in the left upper quadrant by its characteristic location and the configuration of its rugal folds (see Fig. 11-1A). When the patient is in the supine position, gas in the stomach rises to the anteriorly located antrum, while fluid gravitates to the fundus. When the fluid-filled fundus is visible on abdominal

radiographs, it can occasionally be mistaken for a soft tissue mass (see Fig. 11-5A). However, confusion may be eliminated by the use of upright radiographs, which allow gas to enter the gastric fundus (see Fig. 11-1B). The stomach is a valuable landmark for identifying space-occupying lesions in surrounding structures such as the spleen laterally, the liver medially, and the lesser sac and pancreas posteriorly (see Figs. 11-1B and C and 11-5).¹⁷

Figure 11-7 Paracolic gutters and lateral conal fascia. Coned-down view from supine abdominal radiograph shows the left and right paracolic gutters between the transversalis fascia (arrowheads) and lateral conal fascia (large arrows). Small arrows denote the gallbladder.

Small Intestine

The small bowel and its associated mesentery occupy the central portion of the peritoneal cavity.¹⁷ Although transit time through the small bowel is sufficiently rapid to prevent swallowed air from accumulating in normal small bowel loops, these loops may be visible on abdominal radiographs when they contain small amounts of gas (see Fig. 11-1A). In contrast, large amounts of air and fluid in a dilated small bowel indicate prolonged transit time caused by mechanical obstruction or an adynamic ileus. Scattered gas and fluid within normal to minimally dilated small bowel loops may occur in a variety of normal or pathologic conditions, including gastroenteritis, pancreatitis, inflammatory bowel disease, and aerophagia. Unfortunately, considerable interobserver variation occurs in interpretation of small bowel gas. The term *nonspecific gas pattern* has been used to describe abdominal radiographs showing more than the average amount of small bowel gas, without a clear indication of bowel obstruction. However, this term is vague or even misleading and is not helpful to the referring physician; therefore, it should not be used. Instead, radiologists should provide a clear description of the radiographic findings and the most reasonable diagnostic considerations. The gas-filled small bowel is distinguished from the colon by its more central location, smaller caliber, and typical mucosal folds, also known as the valvulae conniventes (see Fig. 11-1A). When visualized, the small bowel folds are usually thin and extend across the entire lumen of the bowel.

Colon

The adult colon usually contains some gas and fecal material and frames the abdomen, with the small bowel located more centrally. The more anterior transverse and sigmoid segments usually contain the greatest amount of gas when the patient is in the supine position. Unlike the valvulae conniventes of the small bowel, the colonic haustral folds are more widely spaced

and usually do not cross the entire lumen¹⁷ (see Fig. 11-1A). The caliber of the colon varies from 3 to 8 cm, with the largest diameter found in the cecum. Persistent cecal diameters of 9 to 10 cm or more may indicate a risk of impending perforation from mechanical obstruction or ileus.²²

The sigmoid and transverse colon are intraperitoneal structures suspended by the sigmoid mesentery and transverse mesocolon, respectively. Conversely, the ascending and descending colon and rectum are retroperitoneal structures, fixed to the posterior abdominal wall. In about 20% of the population, the cecum and a variable portion of the ascending colon have a persistent mesentery.²³ In such cases, the cecum is mobile and its position is more anterior and medial than usual. Although most of these patients are asymptomatic, this anatomic variation predisposes to an ileus, cecal bascule, and cecal volvulus.²⁴ The sigmoid colon is an intraperitoneal structure, but sigmoid diverticula are frequently oriented toward the sigmoid mesentery, so rupture of a diverticulum (with subsequent diverticulitis) usually results in the development of retroperitoneal gas rather than free intraperitoneal air.²³

On upright abdominal radiographs, air-fluid levels in the bowel can be interpreted as a sign of bowel obstruction. However, air-fluid levels in the small bowel and colon may occur in nonobstructive conditions and in normal patients. Air-fluid levels are particularly common in the right side of the colon after cathartic preparation.²⁵

Potential Intraperitoneal Spaces

The peritoneal reflections from the posterior abdominal wall over the viscera give rise to potential spaces in which blood, fluid, or pus may localize in the peritoneal cavity.¹⁷ In the normal abdomen, these compartments are not directly visible on abdominal radiographs, but their location can be inferred from the location of adjacent organs. The right subphrenic space is located between the right hemidiaphragm and liver. It is above the superior reflection of the right coronary ligament and continuous around the lateral edge of the liver with the right subhepatic space. The anterior subhepatic space lies just above the transverse colon and mesocolon and anterior to the right kidney and duodenum. The posterior subhepatic space, also known as Morison's pouch, continues posteriorly and superiorly to the inferior reflection of the coronary ligament. On abdominal radiographs, Morison's pouch overlies the superior pole of the right kidney.¹⁷ This is the most dependent portion of the upper peritoneal cavity with the patient in the supine position and is a frequent site of abscess formation. The subhepatic space is continuous with the right paracolic gutter between the ascending colon and properitoneal fat. The right paracolic gutter is deeper and wider than the left paracolic gutter. Fluid and abscesses are often visible here and can be recognized on abdominal radiographs by separation of the ascending and descending colon from the properitoneal fat (see Fig. 11-6). The left subphrenic space is separated from the right subphrenic space by the falciform ligament, which is a right midclavicular line structure in most patients. This space surrounds the left lobe of the liver and spleen and is limited inferiorly by the phrenicocolic ligament. Below the phrenicocolic ligament, the shallow left paracolic gutter extends inferiorly into the portion of the pelvis lateral to the descending colon (see Fig. 11-7).

The lesser sac of the peritoneal cavity is a potential space in the midabdomen, extending into the left upper quadrant. It is

Figure 11-8 Lesser peritoneal sac. **A.** Axial CT scan of the abdomen in a patient with acute pancreatitis shows fluid posterior to the stomach in the lesser sac, extending into the superior medial recess (*large white arrow*). The fluid is contained on the left by the gastrosplenic ligament (*small arrows*). **B.** The boundaries of the lesser sac (*arrowheads*) are well delineated on a supine abdominal radiograph in another patient with gas in the lesser sac because of an abscess. The superior recess of the lesser sac extends toward the diaphragm just to the right of the spine. The foramen of Winslow is denoted by *open arrows*. A nasogastric tube is present in the stomach. S, spleen; St, stomach. (Courtesy Susan M. Williams, MD, Omaha.)

bounded superiorly by the left coronary ligament, posteriorly by the pancreas, anteriorly by the stomach, lesser omentum, and gastrocolic ligament, and inferiorly by the transverse colon and mesocolon¹⁷ (Fig. 11-8). Its left lateral borders are formed by the gastrosplenic and splenorenal ligaments. The lesser sac opens into the right subhepatic space via the foramen of Winslow at a site just posterior and superior to the duodenal bulb, beneath the free margin of the hepatoduodenal ligament. Dodds and associates described the lesser sac as an area defined by placing the right hand over the epigastrium, with the thumb extended over the midline toward the hilus of the liver and the fingers directed toward the hilum of the spleen.²⁶ The thumb represents the extension of the superior medial recess and the palm and fingers represent the main portion of the lesser sac. Space-occupying lesions or fluid collections in the lesser sac may displace the transverse colon inferiorly and the stomach superiorly, anteriorly, laterally, or medially (see Fig. 11-8).

RETROPERITONEUM AND ABDOMINAL WALL

The anatomy of the retroperitoneal space has been well described by Meyers.²³ It is posterior to the parietal peritoneum and anterior to the transversalis fascia. The retroperitoneal space is divided into three distinct compartments—the perirenal space, posterior pararenal space, and anterior pararenal space.

Perirenal Space: Kidneys and Adrenal Glands

The kidneys, adrenal glands, and abundant fat are located within the left and right perirenal spaces, which are confined by the anterior and posterior layers of renal fascia. It is the perirenal fat that allows visualization of some or all of the renal outlines on abdominal radiographs in most patients (see Fig. 11-5). On the other hand, the adrenal glands are small and not discernible unless they are calcified as a result of previous hemorrhage or granulomatous disease (Fig. 11-9). The upper half of the psoas muscle and the medial aspects of the hepatic and

Figure 11-9 Diaphragmatic crus and calcified adrenal gland. Supine abdominal radiograph shows a calcified right adrenal gland (*black arrow*) and left diaphragmatic crus (*white arrow*). The right diaphragmatic crus is partially visualized just medial to the calcified right adrenal gland.

splenic angles are visualized on abdominal radiographs because of perirenal fat. Obliteration of the perirenal fat by inflammation, blood, or urine therefore obscures visualization of these structures. The medial perirenal space is continuous with the aorta and often fills with blood in patients with ruptured abdominal aortic aneurysms.²⁷ The anterior and posterior layers of perirenal fascia fuse laterally to form the lateroconal fascia, which continues laterally and ventrally to fuse with the parietal peritoneum along the lateral abdominal wall. In patients with abundant fat, the lateroconal fascia may be visible on abdominal radiographs as a thin line separating the posterior pararenal and anterior pararenal fat (Fig. 11-10).²⁸

Figure 11-10 Lateroconal fascia. **A.** Supine abdominal radiograph shows the lateroconal fascia (arrow) along the paracolic gutter as a thin white line extending from the liver tip to the right lower quadrant. **B.** Axial CT scan shows the lateroconal fascia (arrow), which is composed of the anterior and posterior layers of the perirenal fascia that fuse laterally. The ascending colon (AC) is contained within the anterior pararenal space. K, kidney.

Posterior Pararenal Space

The posterior pararenal space is located posterior to the posterior perirenal and lateroconal fascia and is anterior to the transversalis fascia lining the abdominal wall (see Figs. 11-7 and 11-10).¹⁷ This space contains a variable amount of fat, but no organs. Medially, the posterior pararenal space originates at the lateral margin of the psoas muscle and is not continuous across the midline. Laterally, the posterior pararenal fat extends around the flank, joining the properitoneal fat of the lateral abdominal wall to form the so-called flank stripe (Fig. 11-11). The width of the flank stripe is variable and depends on body habitus. The posterior pararenal fat is continuous inferiorly with extraperitoneal fat in the pelvis.

Anterior Pararenal Space: Ascending and Descending Colon, Duodenum, and Pancreas

The anterior pararenal space, which lies anterior to the perirenal space and lateroconal fascia, contains the ascending and descending colon, retroperitoneal duodenum, and pancreas (see Fig. 11-10).¹⁷ In most patients, the ascending and descending colon can be identified by intraluminal fecal material and gas medial to the flank stripes (see Fig. 11-1). Semi-solid fecal material in the cecum and ascending colon often has a characteristic bubbly appearance. The retroperitoneal duodenum is usually not visible on abdominal radiographs unless it is filled with gas because of an ileus, proximal small bowel obstruction, or pancreatitis. The pancreas is also not visualized on abdominal radiographs because it has undulating, lobulated borders that are not outlined by fat. The normal location of the pancreas may be recognized on abdominal radiographs, however, if there is pancreatic calcification because of chronic pancreatitis (Fig. 11-12).

Psoas Muscle

The psoas muscle arises from the T12-L5 vertebrae and extends inferiorly to join the iliac muscle below the iliac crest. It continues as the iliopsoas muscle to the lesser trochanter.¹⁷ Perirenal fat superiorly and posterior pararenal fat below the level of the kidneys outline the lateral margin of the psoas muscle. In about 75% of patients, the psoas muscle is seen

Figure 11-11 Flank stripe. Supine coned-down view of the left side of the abdomen shows the flank stripe (arrows) outlined by properitoneal fat just lateral to the descending colon. This fat is contiguous with the retroperitoneal fat in the posterior pararenal space. When there is no fluid in the left paracolic gutter, it is only a few millimeters in width.

to extend from the diaphragmatic crura to its junction with the iliac muscle (Fig. 11-13; see Fig. 11-1A and B).^{29,30} Fluid in the adjacent retroperitoneal fat may cause obliteration of the margin of the psoas muscle. Loss of one or both shadows of the psoas muscle is a common finding on abdominal

Figure 11-12 Pancreatic calcification. Supine abdominal radiograph shows multiple calcifications outlining the pancreas (arrows) caused by chronic pancreatitis. The pancreas normally is not visible on abdominal radiographs.

Figure 11-13 Psoas muscles. Supine abdominal radiograph shows both psoas muscles (arrows). The lateral margins of the psoas muscle extend inferiorly from the diaphragmatic crura to just below the iliac crest. The medial margins of the psoas muscles are also demonstrated. Note perivesical fat over the dome of the bladder (arrowheads). K, kidney.

radiographs when there is a ruptured abdominal aortic aneurysm, with blood infiltrating the perirenal and posterior paranrenal spaces.

The psoas muscle is optimally visualized when its lateral margin is straight and almost parallel to the x-ray beam. Non-visualization of the psoas margin on abdominal radiographs

must be interpreted with caution. A lumbar scoliosis may result in nonvisualization of the psoas shadow.³⁰ Rotation of the spinal column causes the psoas muscle on the concave side of the spine to assume a more flattened, horizontal configuration. The margin is then more perpendicular to the incident x-ray, so it may not be visible on abdominal radiographs. This phenomenon occurs not only in patients with a structural scoliosis but also in those with a positional scoliosis when muscle spasm causes contraction of the muscles in the flank. When there is a limited amount of retroperitoneal fat, the peritoneal cavity extends posteriorly, so fluid-filled bowel loops may come to lie directly adjacent to the psoas muscle, obscuring its margin. Occasionally, the kidney may also cause segmental nonvisualization of the psoas muscle, particularly in patients with an enlarged spleen that displaces the kidney medially.³⁰ Thus, retroperitoneal or intraperitoneal disease, scoliosis, or even a normal variation can obscure the psoas margin.

Quadratus Lumborum Muscle

Lateral and parallel to the psoas muscle is the lateral margin of the quadratus lumborum muscle, often seen to extend to its origin at the iliac crest. The quadratus lumborum muscle is part of the posterior abdominal wall and lies dorsal to the transversalis fascia, which passes between it and the psoas muscle.¹⁷ However, visualization of the quadratus lumborum muscle depends on the integrity of the posterior paranrenal fat, which outlines its lateral margin.

Diaphragmatic Crura

The diaphragmatic crura may outline retroperitoneal fat that is continuous with the origin of the psoas muscle (see Fig. 11-9). The crura are best seen on abdominal radiographs when the x-ray beam is centered near the level of the diaphragm.³¹ Occasionally, posterior paranrenal fat continues superiorly beneath the diaphragm, simulating pneumoperitoneum. In such cases, a left lateral decubitus view should differentiate pneumoperitoneum from paranrenal fat because the lucency associated with fat is not affected by changes in patient position.

PELVIS

Delineation of the various muscles and visceral structures in the pelvis is highly variable and depends on a variety of factors, including the amount of extraperitoneal pelvic fat, bowel contents, degree of bladder distention, position of the patient, and body habitus. As a result, these structures are not always identified, even in the absence of pelvic disease.

Piriformis Muscle

The piriformis muscle is in the superolateral posterior aspect of the pelvis.¹⁷ Its inferior margin can be visualized as a smooth convex interface passing from the sacrum to the greater sciatic foramen (Fig. 11-14). Just caudal to the piriformis muscle, the sciatic nerve passes out of the pelvis. Internal hernias can extend through the greater sciatic foramen into the buttocks; these hernias may contain bowel, bladder, or ureter.

Obturator Internus Muscle

The obturator internus muscle abuts the lateral pelvic sidewall and surrounds the greater portion of the obturator

foramen.¹⁷ It originates from the pubic ramus, ischium, and pelvic wall, and its tendon exits the pelvis at the lesser sciatic foramen, just below the sacrospinous ligament. The obturator internus muscle may be identified on abdominal radiographs as a result of subperitoneal fat that surrounds

Figure 11-14 Piriformis muscle. Coned-down view of the pelvis from a supine abdominal radiograph shows the inferior margins of the piriformis muscles bilaterally (large arrows). Inferior to the piriformis muscles is the edge of the sacrospinous ligament and associated coccygeus muscles (small arrows) outlining the roof of the ischiorectal fossa. The perineum forms the medial boundary of the ischiorectal fossa (arrowheads).

it superiorly and ischiorectal fat that surrounds it inferiorly, below the origin of the levator ani muscle (Fig. 11-15). The obturator canal is located at the superolateral aspect of the obturator foramen; this canal transmits the obturator vessels and nerve.³² Hernias may occur at this site, particularly in older women (Fig. 11-16). These hernias often produce characteristic neuralgia in the thigh secondary to nerve compression.³²⁻³⁴

Sacrospinous Ligament and Coccygeus Muscle

The edge of the sacrospinous ligament and associated coccygeus muscle are outlined by underlying ischiorectal fat.¹⁷ These structures are located just inferior to the piriformis muscle and may be seen as a smooth band arching from the tip of the sacrum to the ischial spine (see Fig. 11-14).

Ischiorectal Fossa

The left and right ischiorectal fossae are wedge-shaped, subcutaneous fatty masses, with their bases at the perineum and their apices at the junction of the obturator internus and levator ani muscles.¹⁷ They are often visible on abdominal radiographs (see Fig. 11-14).

Gluteus Maximus Muscle

The gluteus maximus muscle forms the posterior border of the ischiorectal fossa.¹⁷ The medial edge of this muscle is outlined by subcutaneous fat, so it often appears on abdominal radiographs as a smooth line extending inferiorly and laterally from the tip of the sacrum.

Pelvic Viscera

The superior and lateral aspects of the urinary bladder are outlined by perivesical fat (Fig. 11-17; see Fig. 11-13). The uterus may also be visible in the pelvis just above this fat, particularly if the fundus is anteverted and indents the adjacent fat. This perivesical fat can be used to help identify fluid in

Figure 11-15 Obturator internus muscles.

A. Coned-down view of the pelvis from a supine abdominal radiograph shows the obturator internus muscles (arrows). **B.** Axial CT scan of the pelvis shows the superior portion of the obturator internus muscles (arrows) outlined by extra-peritoneal fat. **C.** Axial CT scan more caudally shows the obturator internus muscles (white arrows) outlined by ischiorectal fat. The left and right ischiorectal fossae are bounded by the levator ani muscles (black arrows) and obturator internus muscles.

Figure 11-16 Obturator hernia causing small bowel obstruction. **A.** Axial CT of the pelvis in an older woman shows a left obturator hernia (arrow). Also note the left obturator internus muscle (arrowhead). **B.** Coronal CT of the pelvis shows the left obturator hernia (arrow), with dilated small bowel (arrowheads) proximal to the obstructing hernia.

Figure 11-17 Ascites demarcated by perivesical fat. **A.** Coned-down view of pelvis from a supine abdominal radiograph shows evidence of ascites with increased density above the perivesical fat (arrows). Also note how the small bowel is displaced medially by ascitic fluid in the abdomen. **B.** Increased density is again seen in the paravesical spaces above the bladder on a supine abdominal radiograph in another patient with ascites. Note how the top of the bladder is outlined by perivesical fat (arrowheads). **C.** Axial CT of the pelvis in the same patient as in **B** confirms the presence of ascites (black arrows) around the bladder (B). Also note fluid (arrowheads) behind the bladder, surrounding the uterus (U).

the pelvis (see Fig. 11-17). Prostatic calculi will identify the position of the prostate gland, which is caudal to the urinary bladder and usually not seen on abdominal radiographs. Posterior to the bladder and uterus, the rectum can usually be recognized by the presence of intraluminal gas and stool (see Fig. 11-1).

Acknowledgment

The author would like to acknowledge and thank Susan M. Williams, MD, for giving permission to use parts of her excellent Chapter 10 from the second edition of this textbook.

Even with the widespread availability of cross-sectional imaging studies, abdominal radiography remains a common imaging test in modern radiology practice. Although CT and ultrasound provide more information about acute abdominal conditions, abdominal radiography has the advantages of relatively low cost and ease of acquisition and can readily be performed on acutely ill or debilitated patients, so it remains a valuable study for the trained and perceptive observer. The abdominal radiograph has also been called a KUB—*k*idneys, *u*reters (which are not visible), and *b*ladder. The term *flat plate of the abdomen* is dated and refers to a time when glass plates were used to produce images. Other terms include *plain film of the abdomen* and *abdominal plain film*, but with the widespread use of digital imaging and picture archiving communication systems (PACS) for interpretation of the images, *abdominal radiograph* has become the most appropriate term.

A wealth of diagnostic information can be obtained from correct interpretation of abdominal radiographs, and several excellent texts are available on the subject.¹⁻³ This chapter focuses on the abnormalities of gas and soft tissues that can be detected on abdominal radiographs.

Normal Bowel Gas Patterns

The intestinal tract in adults usually contains less than 200 mL of gas. Intestinal gas has three sources—swallowed air, bacterial production, and diffusion from the blood. In the supine patient, gas rises and accumulates in anteriorly placed segments of intestine, including the antrum and body of the stomach, transverse colon, and sigmoid colon. Gas may also be present in the remaining colon, particularly the rectum. Radiographic evaluation of intestinal gas should include the following: (1) identification of the bowel segments containing gas; (2) assessment of the caliber of these segments; (3) assessment of the most distal point of passage of gas; and (4) evaluation of the bowel contour outlined by gas.

The normal bowel gas pattern is readily visible on supine abdominal radiographs (Fig. 12-1). The first collection of gas encountered from the top of the radiograph is usually in the antrum and body of the stomach. Gas may also be seen in the transverse colon immediately inferior to the stomach. Gas in the ascending and descending portions of the colon usually occupies the lateral margins of the peritoneal cavity. The sigmoid colon occupies the inferior aspect of the abdomen and is often recognized by its characteristic shape and haustral folds. Rectal gas occupies a midline position in the pelvis and generally extends to the level of the pubic symphysis. The gas-filled small bowel tends to occupy the central portion of the abdomen and has a smaller caliber than the colon.

Although the location of intestinal gas is helpful in differentiating colon from small bowel, recognition of intestinal folds is also important. Haustral folds in the colon are normally 2 to 3 mm in width and occur at intervals of 1 cm, whereas the circular small bowel folds (also known as plicae circulares) are 1 to 2 mm in width and occur at intervals of 1 mm. In general, the small bowel is smaller than 3 cm in diameter and the colon is smaller than 5 cm in diameter.

Intestinal gas is a natural contrast agent for the interpretation of abdominal radiographs. When the patient is in the supine position, the gastric antrum and body tend to distend with air. A long narrowed segment of air-filled stomach may indicate an infiltrating process such as linitis plastica. Gastric ulcers and masses are also occasionally visible (Fig. 12-2A). In the colon, gas may outline a narrowed lumen from ulcerative or granulomatous colitis, thickened haustral folds from ischemia (Fig. 12-2B), or even a polypoid or annular carcinoma (see Fig. 12-5A).

Abnormal Bowel Gas Patterns

GASTRIC OUTLET OBSTRUCTION

Gastric outlet obstruction may be manifested on abdominal radiographs by a dilated stomach containing air, fluid, and/or debris. The amount of gastric distention depends not only on the degree of obstruction, but also on the duration of obstruction, position of the patient, and frequency of emesis. A dilated, air-filled stomach is usually recognized without difficulty because of its characteristic shape and location associated with

Figure 12-1 Normal bowel gas pattern. The most superior collection of intestinal gas is contained in the stomach (*large arrows*). Gas and stool outline the ascending and transverse colon (*small arrows*). Gas can also be seen in a portion of the small intestine (*curved arrow*).

inferior displacement of the transverse colon. Occasionally, a massively dilated, fluid-filled stomach can mimic the appearance of ascites or hepatomegaly. A small amount of air is almost always present within the stomach, however, so an upright radiograph of the chest or abdomen should demonstrate an air-fluid level within the gastric lumen.

The distal gastric antrum and pyloric region are the usual sites of gastric outlet obstruction. The most common causes of obstruction include acute edema and spasm from an ulcer in the distal antrum or pyloric channel or chronic antral narrowing secondary to scarring from a previous ulcer. Other causes of gastric outlet obstruction include an infiltrating antral carcinoma and, less commonly, scarring from granulomatous disease, radiation, or previous caustic ingestion.

Not all patients with gastric distention have mechanical obstruction. The stomach may also be dilated because of gastroparesis or gastric atony from diabetes (*gastroparesis diabetorum*), which is almost always associated with a peripheral neuropathy.⁴ Other causes of gastric dilation include morphine and other narcotic agents, hypokalemia, uremia, porphyria, lead poisoning, and previous truncal vagotomy. Pancreatitis or gastritis may also result in reflex gastric atony, and general anesthesia may occasionally cause marked gastric dilation.

Patients with obstructive lesions in the duodenum may also present with findings of gastric outlet obstruction. The duodenum may be filled with fluid, so it is not readily visible on supine radiographs. Left lateral decubitus views of the abdomen may allow air to enter the dilated duodenum, indicating that the obstruction is distal to the pylorus. When fluoroscopic barium studies are performed in patients with suspected gastric outlet obstruction, the duodenum should be carefully examined if the stomach appears normal.

ADYNAMIC ILEUS

The term *adynamic ileus* refers to dilated bowel in the absence of mechanical obstruction. It is used synonymously with the terms *paralytic ileus* and *nonobstructive ileus*. A more specific term, *postoperative ileus*, is limited to patients in whom recent abdominal surgery is responsible for this condition. All these terms refer to a state of decreased or absent intestinal peristalsis, causing swallowed air to accumulate in dilated bowel.⁵ An adynamic ileus is typically manifested on abdominal radiographs

Figure 12-2 Abnormal bowel contours. A. Gas in the stomach outlines a mass (*white arrows*) on the lesser curvature, with an irregular central gas collection (*black arrows*) representing a large benign ulcer with surrounding edema. **B.** Air in the transverse colon outlines thickened haustral folds (*arrows*) in a patient with colonic ischemia. (*A* courtesy Timothy J. Cole, MD, Richmond, VA.)

by a dilated small bowel and colon, with multiple air-fluid levels on upright or horizontal beam decubitus views, so the presence of a dilated colon allows this condition to be differentiated from mechanical small bowel obstruction, in which only the small bowel is affected (see later, “[Small Bowel Obstruction](#)”). Sometimes, however, an adynamic ileus is confined to the small bowel, mimicking the findings of small bowel obstruction ([Fig. 12-3](#)), so the absence of colonic distention in no way excludes this condition. Apart from recent abdominal surgery, an adynamic ileus may result from a wide variety of causes, including electrolyte imbalances, sepsis, generalized peritonitis, blunt abdominal trauma, and infiltration of the mesentery by tumor.⁶

Other patients may have a localized ileus (also known as a sentinel ileus) related to acute inflammatory conditions in adjacent areas of the abdomen, including the right lower quadrant in patients with appendicitis, left lower quadrant in patients with diverticulitis, right upper quadrant in patients with cholecystitis, and mid upper abdomen or left upper quadrant in patients with pancreatitis.

Figure 12-3 Postoperative ileus mimicking small bowel obstruction. **A.** Supine abdominal radiograph shows multiple loops of dilated small bowel with a paucity of colonic gas. **B.** Upright radiograph shows differential air-fluid levels. Although the radiographic findings are suggestive of small bowel obstruction, this patient had a postoperative ileus involving the small bowel (note the longitudinal row of skin staples from recent abdominal surgery).

Figure 12-4 Small bowel obstruction. **A.** Supine radiograph shows dilated small bowel loops in the upper abdomen, with a paucity of colonic gas. **B.** Upright radiograph demonstrates multiple air-fluid levels. Small amounts of gas trapped between small bowel folds in the left midabdomen (arrows) produce the string of pearls sign.

SMALL BOWEL OBSTRUCTION

Small bowel obstruction is often difficult to diagnose on abdominal radiographs. False-positive and false-negative rates of 20% have been reported in the diagnosis of small bowel obstruction based solely on the radiographic findings.⁷ The diagnostic sensitivity can be increased by correlating the radiographs with the presence or absence of bowel sounds. Sequential radiographs over 12 to 24 hours may be helpful in demonstrating an evolving obstructive pattern.

When the small intestine becomes completely obstructed, accumulation of swallowed air and intestinal secretions causes proximal dilation of bowel. At the same time, intestinal peristalsis progressively eliminates bowel contents distal to the site of obstruction within 12 to 24 hours. As a result, small bowel obstruction is typically characterized on supine abdominal radiographs by dilated, gas-filled small bowel loops larger than 3 cm in diameter, with little or no gas in the colon or small bowel distal to the site of obstruction ([Fig. 12-4A](#)).

Upright and decubitus abdominal radiographs typically reveal multiple air-fluid levels in the dilated small bowel because of accumulation of gas and fluid proximal to the obstruction (Fig. 12-4B).

In his classic work on the acute abdomen, Frimann-Dahl stated that the presence of air-fluid levels at two different heights in the same loop of small bowel indicates a hyperperistaltic small intestine and is therefore a sign of small bowel obstruction.⁸ However, subsequent investigators have found that differential air-fluid levels may be present in any tubular viscus containing air and fluid. Thus, air-fluid levels should be recognized as a nonspecific finding that can be seen with a mechanical obstruction or adynamic ileus.

As small bowel obstruction progresses, gas-filled small bowel loops proximal to the site of obstruction become more dilated and tend to have a horizontal orientation in the central portion of the abdomen, producing a classic stepladder appearance. However, the amount of gaseous distention of these loops depends not only on the degree of obstruction, but also on the duration of obstruction, amount of air swallowing or emesis, and use of nasogastric suction for decompression. In some patients with small bowel obstruction who swallow relatively little air, supine abdominal radiographs may be unrevealing, whereas upright or decubitus abdominal radiographs (i.e., horizontal beam views) will show multiple air-fluid levels within small bowel loops proximal to the site of obstruction. In other patients, small amounts of gas trapped between the small bowel folds on upright or decubitus abdominal radiographs may be recognized by tiny bubbles of gas lined up along the nondependent surface of the bowel, also known as the **string of pearls or string of beads sign** (see Fig. 12-4B). This sign is seldom seen in patients with an adynamic ileus and should therefore suggest a mechanical small bowel obstruction. Finally, when patients swallow little or no air, abdominal radiographs may reveal multiple tubular, sausage-shaped soft tissue densities representing fluid-filled loops of small bowel without any intraluminal gas in the small bowel or colon, producing a so-called gasless abdomen. In general, the absence of colonic gas should suggest the possibility of a developing small bowel obstruction because gas is normally present in the colon in the absence of obstruction.

Most small bowel obstructions are caused by postoperative adhesions. Such adhesions may occur as early as 1 week after surgery, but more typically there is a remote history of surgery. In the absence of a surgical history, an obstructing hernia should be suspected. Of these hernias, 95% are external (inguinal, femoral, umbilical, or incisional). The presence of air-filled bowel below either pubic ramus should suggest the possibility of an obstructing inguinal hernia. Other less common causes of small bowel obstruction include small bowel tumors, ectopic gallstones, acute appendicitis and, occasionally, intestinal parasites or bezoars.⁹⁻¹³

It may not be possible to distinguish mechanical obstruction from an adynamic ileus on the basis of a single set of abdominal radiographs. If immediate surgery is not contemplated, further radiographic work-up with computed tomography (CT) is usually indicated.¹⁴ This topic is discussed in detail in Chapter 46. Barium studies may also be helpful when abdominal radiographs reveal findings of low-grade or partial small bowel obstruction.

COLONIC ILEUS

Acute colonic pseudo-obstruction (also known as Ogilvie's syndrome) was first described in 1948 by Ogilvie,¹⁵ who postulated that progressive colonic dilation is caused by interruption of sympathetic innervation with unopposed parasympathetic innervation of the colon. The most common clinical presentation is acute abdominal distention, usually occurring within 10 days of the onset of the precipitating pathologic process. Intra-abdominal inflammation, alcoholism, cardiac disease, burns, retroperitoneal disease, trauma, and pregnancy with spontaneous delivery or cesarean section have been described as causes of Ogilvie's syndrome.¹⁶⁻¹⁹

Abdominal radiographs may reveal marked colonic distention, which is typically confined to the cecum, ascending colon, and transverse colon. Occasionally, however, gas may extend to the level of the sigmoid colon. The underlying clinical condition and rapid onset of colonic distention usually suggest the diagnosis of colonic pseudo-obstruction, but a limited contrast enema may be required to rule out obstructing lesions in the colon.

Prediction of impending perforation of the cecum, as judged by cecal diameter, is fraught with difficulty because the risk of cecal perforation depends not only the degree of distention, but also on the duration—that is, the risk is considerably less in patients with long-standing cecal distention than in those with an acute increase in cecal caliber. Although some authors have indicated that a cecal diameter of 9 to 12 cm suggests impending perforation, cecal diameters of 15 to 20 cm are commonly observed in patients who recover spontaneously from Ogilvie's syndrome.^{18,20-22} Serial radiographs showing a change in cecal diameter at 12- to 24-hour intervals may be more helpful than a single radiograph showing a dilated cecum. Intravenous (IV) neostigmine is sometimes used for the initial treatment of these patients.^{23,24} Prolonged cecal distention beyond 2 to 3 days should prompt colonoscopic or surgical decompression.²⁵ The presence of intramural gas in the region of the dilated cecum should strongly suggest infarction and impending perforation.

COLONIC OBSTRUCTION

More than 50% of colonic obstructions are caused by annular carcinomas of the colon.^{26,27} The obstruction usually occurs in the sigmoid colon, where the bowel tends to have a narrower caliber and the stool is more solid. Conversely, cecal carcinomas and those in the ascending colon are less likely to cause obstruction because of the wider caliber of the bowel and more liquid character of the stool.

Colonic obstruction is typically manifested on abdominal radiographs by dilated, gas-filled loops of colon proximal to the site of obstruction and a paucity or absence of gas in the distal colon and rectum (Fig. 12-5A). Air-fluid levels may be seen on upright or decubitus views (Fig. 12-5B). Abdominal CT may be performed to confirm the presence of obstruction and determine its underlying cause (Fig. 12-5C). In patients with a competent ileocecal valve, the colon (especially the cecum) may become markedly dilated, and little or no gas may be seen in the small bowel. As the cecal diameter increases, the risk of perforation also increases. In various series, colonic perforation has been reported in as many as 7% of all large bowel obstructions and 2% of obstructing colonic carcinomas.²⁸⁻³⁰ Perforations sometimes occur at the site of obstruction, but usually

Figure 12-5 Colonic obstruction resulting from colonic carcinoma.
A. Supine radiograph shows dilated colon with a soft tissue mass (arrows) in the sigmoid colon.
B. Upright radiograph shows air-fluid levels in the colon proximal to the site of obstruction.
C. CT confirms sigmoid colon cancer (arrows).

result from progressive ischemia in the dilated colon or cecum proximal to the obstruction.³¹

An incompetent ileocecal valve allows gas to reflux into the small bowel, decompressing the colon, so the radiographic findings can mimic those of small bowel obstruction. Nevertheless, the distinction between colonic obstruction and small bowel obstruction has important implications because orally administered barium can inspissate above an unsuspected colonic obstruction. Abdominal CT or a single-contrast barium enema should therefore be considered in any patient with apparent obstruction of the distal small bowel on abdominal radiographs (especially an older patient who has no prior history of abdominal surgery) to rule out an underlying colonic or cecal carcinoma as the cause of obstruction.

CLOSED LOOP OBSTRUCTION

A closed loop obstruction refers to a segment of bowel that is obstructed at two points. Closed loop obstructions usually involve the small bowel and are caused by adhesions, internal hernias, or volvulus. The findings on abdominal radiographs are often nonspecific. Occasionally, there may be a disproportionately dilated, gas-filled loop of small bowel that has the

appearance of a coffee bean. Persistence of the dilated loop on sequential radiographs over several days should increase concern for a closed loop obstruction. Vascular compromise may lead to edema and thickening or effacement of the folds within this loop. If the obstructed segment fills with fluid, a rounded soft tissue density outlined by intra-abdominal fat produces a pseudotumor appearance. A history of intermittent, crampy abdominal pain replaced by steady, unrelenting pain should suggest a closed loop obstruction with vascular compromise. Nevertheless, a definitive diagnosis can be made only at surgery.

VOLVULUS

Any segment of intestine that has a mesenteric attachment has the potential to undergo a volvulus. Some patients may have intermittent intestinal twists associated with recurrent episodes of abdominal pain or emesis. If the twist is greater than 360 degrees, it is unlikely to resolve spontaneously. In some cases, air and intestinal contents may enter the twisted segment of bowel, producing abdominal distention and pain. The risk of vascular compromise in the twisted segment is more important than the mechanical effects of the volvulus. Severe vascular

compromise may result in necrosis and perforation of bowel, causing sepsis and death. Gastric volvulus is discussed in Chapter 34. Colonic volvulus may involve different segments of the colon, as discussed in the following sections.

Sigmoid Volvulus

Sigmoid volvulus constitutes 60% to 75% of all cases of colonic volvulus. Overall, sigmoid volvulus accounts for 1% to 2% of all intestinal obstructions in the United States.^{32,33} In some areas of South America and Africa, the incidence of sigmoid volvulus is extraordinarily high, reportedly because of a high-fiber diet and the resultant large, bulky stools, producing a chronically dilated, elongated sigmoid colon that predisposes patients to this type of volvulus. The incidence of sigmoid volvulus also appears to be higher in people living at higher altitudes in South America and Africa. In the United States, sigmoid volvulus tends to occur in older men and residents of nursing homes and mental hospitals, in whom chronic constipation and obtundation from medication are predisposing factors for gaseous distention of the sigmoid colon and stretching of the sigmoid mesocolon.

Patients with sigmoid volvulus typically present with abdominal pain and distention resulting from colonic obstruction. Obstipation and vomiting are also common findings. The symptoms are usually acute, but they may have a gradual onset in some patients.

Findings on abdominal radiographs are diagnostic of sigmoid volvulus in about 75% of patients with this condition. The classic radiographic appearance consists of a massively dilated loop of sigmoid colon that has an inverted U configuration and absent haustral folds and extends superiorly above the transverse colon into the left upper quadrant beneath the left hemidiaphragm (even elevating the diaphragm), with air-fluid levels in both the ascending and descending limbs of this loop. However, the dilated bowel can be in the midline or can even extend into the right upper quadrant (Fig. 12-6). Although there often is associated dilation of the more proximal colon, disproportionate dilation of the sigmoid in relation to the remaining colon and extension of the sigmoid colon superiorly above the transverse colon are important diagnostic features for differentiating sigmoid volvulus from simple colonic obstruction.³⁴ The apposed inner walls of the sigmoid colon may occasionally form a dense white line that points toward the pelvis. The absence of rectal gas is also an important differentiating feature. If prone or decubitus views of the pelvis show free passage of gas into the rectum, sigmoid volvulus therefore is extremely unlikely.

A contrast enema may occasionally be required in patients with suspected sigmoid volvulus. A low-pressure barium enema performed without inflation of a rectal balloon should demonstrate smooth, tapered narrowing, or beaking, at the rectosigmoid junction with associated obstruction.

Patients with sigmoid volvulus sometimes can be successfully treated by placement of a rectal tube for decompression of the dilated sigmoid loop. Patients who have persistent sigmoid dilation despite rectal tube placement and those who develop recurrent sigmoid volvulus may require surgical resection of the sigmoid colon for definitive treatment of this condition.

Cecal Volvulus

The term *cecal volvulus* refers to a condition caused by a rotational twist of the right colon on its long axis associated with

Figure 12-6 Sigmoid volvulus. Supine abdominal radiograph in a patient with sigmoid volvulus shows a massively dilated loop of sigmoid colon extending superiorly into the right upper quadrant and elevating the right hemidiaphragm, with no gas seen in the rectum.

mobility of the ascending colon, so the cecum flips into the midabdomen or left upper quadrant. Cecal volvulus can occur only when the right colon is incompletely fused to the posterior parietal peritoneum, an embryologic variant present in 10% to 37% of adults.³⁵⁻³⁷ These patients have a persistent mesentery on the ascending colon and, because of its greater mobility, the ascending colon can twist on its mesentery, producing a volvulus. Nevertheless, it should be recognized that the vast majority of patients with this embryologic variant never develop cecal volvulus. The term *cecal volvulus* is actually a misnomer because the twist is distal to the ileocecal valve. Cecal volvulus is less common than sigmoid volvulus, accounting for 2% to 3% of all colonic obstructions and about one third of all cases of colonic volvulus.

The characteristic findings of cecal volvulus, which are present on abdominal radiographs in about 75% of patients, consist of a markedly dilated, gas-filled cecum containing a single air-fluid level in an ectopic location (Fig. 12-7), usually with the cecal apex in the left upper quadrant. The medially placed ileocecal valve may produce a soft tissue indentation, so the gas-filled cecum has the appearance of a coffee bean or kidney. Usually, little gas is seen distally in the colon. If the ileocecal valve is incompetent, refluxed gas in the small bowel may erroneously suggest a small bowel obstruction. The diagnosis may be confirmed by a contrast enema or abdominal CT scan showing the typical beaking at the point of the volvulus in the mid-ascending colon.³⁸ Cecal volvulus may occur in a

Figure 12-7 Cecal volvulus.

A. Supine abdominal radiograph shows a markedly dilated viscus in the left upper quadrant, representing the obstructed cecum. Also note multiple loops of dilated small bowel. **B.** Upright radiograph shows the caput of the cecum superiorly (small thick arrows) and ileocecal valve (thin arrow), with a single air-fluid level in the dilated cecum.

variety of settings, including colonoscopy, barium enema, obstructive lesions in the distal colon, and pregnancy.³⁹⁻⁴¹

In 1938, Weinstein described a condition known as cecal bascule, which involved folding of the right colon without twisting, so the cecum occupied a position in the midabdomen.⁴² The term *bascule* is derived from *bascula*, the Latin word for “scale.”⁴¹ The point at which the ascending colon is folded represents the fulcrum of the scale. This entity also requires a persistent mesentery on the ascending colon.⁴³ The concept of a cecal bascule was challenged by Johnson and colleagues,²⁵ who believed that these patients have a focal adynamic ileus of the cecum. Of their patients, 20% had cecal perforation. They emphasized that the duration of cecal distention was more important than cecal diameter in predicting impending perforation. Whether cecal bascule represents an actual anatomic folding of the right colon or an adynamic ileus is not as important as the recognition that a dilated, ectopically located cecum may be a source of abdominal symptoms and potential cecal perforation.

Cecal volvulus should be differentiated from a prolonged colonic ileus in bedridden patients with a persistent mesentery on the ascending colon because the anteriorly located cecum in these patients may become disproportionately dilated, mimicking the appearance of a cecal volvulus. This has been described as cecal pseudovolvulus. Unlike patients with true cecal volvulus, however, cecal pseudovolvulus is associated with diffuse colonic distention, so it is usually possible to differentiate these conditions on the basis of the radiographic findings.

Transverse Colon Volvulus

Volvulus of the transverse colon is an uncommon condition, accounting for only about 4% of all cases of colonic volvulus in the United States.³³ As with sigmoid volvulus, elongation of the transverse mesocolon and close approximation of the hepatic

and splenic flexures may allow the transverse colon to twist on its mesenteric attachment. Failure of normal fixation of the mesentery may lead to increased mobility of the ascending colon and hepatic flexure, predisposing these patients to volvulus of the transverse colon.^{44,45} Compression of the duodenojejunal junction at the root of the mesentery may cause severe vomiting. Mortality rates as high as 33% have been reported in these individuals.⁴⁶

Abdominal radiographs are usually not helpful for patients with volvulus of the transverse colon and may erroneously suggest sigmoid volvulus. A barium enema may confirm the diagnosis if it shows typical beaking and obstruction at the level of the transverse colon. Two separate air-fluid levels can sometimes be seen in the dilated transverse colon, a finding that helps differentiate volvulus of the transverse colon from cecal volvulus.

Splenic Flexure Volvulus

Splenic flexure volvulus is the least common type of colonic volvulus. Postoperative adhesions, chronic constipation, and congenital or postsurgical absence of the normal peritoneal attachments of the splenic flexure may predispose patients to this uncommon condition.⁴⁷⁻⁵⁰ Abdominal radiographs may reveal a dilated, featureless, air-filled loop of bowel in the left upper quadrant that is separate from the stomach, with air-fluid levels in the transverse colon and cecum. When a splenic flexure volvulus is suspected, a single-contrast barium enema may be performed for a more definitive diagnosis.

Appendicitis

The development of acute appendicitis requires obliteration of the appendiceal lumen, usually by a concretion that may be visible on abdominal radiographs. The concretion has been

called a fecalith or coprolith, but the preferred term is *appendicolith*. This concretion forms around a nidus such as a piece of vegetable matter. Inspissated feces and calcium salts may adhere to the nidus, so it eventually reaches a size that occludes the appendiceal lumen. Accumulation of mucus proximal to the obstruction may distend the appendix, causing inflammation, ischemia, and perforation.

Some investigators believe that abdominal radiographs are of little value in patients with suspected appendicitis.^{51,52} Nevertheless, such radiographs are frequently obtained as the first imaging study in patients presenting to the emergency room with right lower quadrant pain.

MAJOR SIGNS OF APPENDICITIS

Signs of appendicitis on abdominal radiographs include the following:

Appendicolith. The presence of an appendicolith is the single most helpful sign of appendicitis on abdominal radiographs. Appendicoliths are found in about 10% of patients with acute appendicitis, typically appearing as round or ovoid calcified densities that are frequently laminated (Fig. 12-8). Most appendicoliths range from 1 to 2 cm in size, but some may be as large as 4 cm.⁵³⁻⁵⁶ They are usually in the right lower quadrant but can also be located in the pelvis or even in the right or left upper quadrant. The presence of an appendicolith has important implications for patients with appendicitis because it indicates a greater likelihood of superimposed perforation and abscess formation.

Figure 12-8 Acute appendicitis with partial small bowel obstruction. Supine abdominal radiograph shows a laminated appendicolith (arrows) in a patient with appendicitis. Also note a paucity of bowel gas in this region and dilated small bowel more proximally because of associated small bowel obstruction.

Abnormal Bowel Gas Pattern. About 25% of patients with appendicitis have an abnormal bowel gas pattern, usually an adynamic ileus, but occasionally a partial or even complete small bowel obstruction may be present (see Fig. 12-8).⁵⁷ An adynamic ileus occurs as a response to focal inflammation and may be localized to the right lower quadrant (also known as a sentinel ileus). Air-fluid levels in the jejunum have also been described in up to 50% of cases.⁵⁸ A dilated transverse colon may also be seen as an early sign of appendiceal perforation.⁵⁹ Mechanical obstruction may occur if the terminal ileum is compressed by the appendix or narrowed by adhesive bands.

Abnormal Cecum and Ascending Colon. Localized inflammation and edema may cause thickening of the cecal wall and widening of haustral folds in this region. An air-fluid level may also be present in the cecum on upright or decubitus abdominal radiographs, but this finding is transient and nonspecific.

Extraluminal Soft Tissue Mass. A soft tissue mass can be found in up to one third of patients with perforation. It may be caused by some combination of edema, fluid, and abscess formation in the right lower quadrant. The presence of mottled or loculated extraluminal gas within this soft tissue mass should strongly suggest an abscess.

Gas in the Appendix. This sign has been described as one of acute appendicitis, even though the pathophysiology of the disease would more likely result in an absence of appendiceal gas.⁶⁰ Usually, an air-filled appendix is a normal finding, simply reflecting the position of the appendix in relation to the cecum, because an ascending retrocecal appendix is more likely to contain gas.⁶¹

Free Intraperitoneal Air. A ruptured appendix rarely may lead to the development of a small amount of free intraperitoneal air. The obstructed appendiceal lumen prevents larger collections of gas from escaping into the peritoneal cavity, except in the case of a ruptured gas-containing abscess.^{62,63}

Obliteration of Normal Fat Planes. Inflammation and edema may alter the water content of surrounding fat and obscure the normal fat planes of the psoas muscle, obturator muscle, or properitoneal flank stripe. This finding is nonspecific and is usually associated with other signs of appendicitis on abdominal radiographs.

Scoliosis of the Lumbar Spine. Some patients with appendicitis may develop a lumbar scoliosis as a result of splinting. This finding is nonspecific, however, and can be related to patient positioning.

Surgeons have long believed that false-negative laparotomies are acceptable in some patients with right lower quadrant pain because of the serious, potentially life-threatening complications of untreated acute appendicitis. However, cross-sectional imaging studies such as CT and ultrasound have significantly improved the preoperative diagnosis of appendicitis (see Chapter 56).

Toxic Megacolon

Toxic megacolon, or toxic dilation of the colon, may be diagnosed on the basis of a dilated colon on abdominal radiographs

in patients with fever, tachycardia, and hypotension. Toxic megacolon is traditionally associated with ulcerative colitis, but it can also occur in patients with granulomatous colitis, amebiasis, cholera, pseudomembranous colitis, cytomegalovirus colitis, and ischemic colitis. Toxic megacolon develops in 5% to 10% of patients with ulcerative colitis, but in only 2% to 4% of patients with granulomatous colitis.⁶⁴⁻⁶⁷ The duration of the underlying disease has no relationship to the development of toxic megacolon. In fact, 70% of patients with toxic megacolon develop this complication during their first episode of colitis.

When toxic megacolon is suspected on clinical grounds, it is important to assess not only the degree of colonic dilation on abdominal radiographs, but also the appearance of the colonic mucosa outlined by air and the presence or absence of free intraperitoneal air. In general, the transverse and ascending portions of the colon tend to become disproportionately dilated, but this is more a reflection of their anterior position within the abdomen or their underlying capacity to dilate than of a greater predisposition to disease.⁶⁸ The upper limit of normal for the diameter of the transverse colon is about 6 cm, whereas the diameter of the transverse colon typically ranges from 6 to 15 cm in patients with toxic megacolon (Fig. 12-9).⁶⁹ A nodular mucosa may be visible in the dilated transverse colon as a result of inflammatory pseudopolyps in patients with ulcerative colitis (see Fig. 12-9).⁷⁰

Colonic perforation occurs in 30% to 50% of patients with toxic megacolon and is associated with a high mortality rate.^{66,71} Thus, a delayed diagnosis of toxic megacolon on

Figure 12-9 Toxic megacolon. There is marked colonic distention in a patient with ulcerative colitis and toxic megacolon. Note the nodular mucosal contour (arrows) in the transverse colon.

abdominal radiographs may have disastrous consequences for these individuals. An increased amount of gas in the small bowel in patients with severe colitis has also been associated with an increased likelihood of developing this condition.⁷²

The diagnosis of toxic megacolon usually is made based on a combination of the clinical and plain film findings, so a contrast enema does not need to be performed in these patients. Although some patients with suspected toxic megacolon have undergone barium enemas, most authors believe that such examinations are contraindicated because of the risk of perforation.⁷³ When toxic megacolon is suspected, CT may be performed to depict the underlying colitis and detect life-threatening complications such as colonic perforation.⁷⁴

Pneumoperitoneum

The presence of free intraperitoneal air (also known as pneumoperitoneum) is an important radiographic observation that usually indicates bowel perforation in patients with an acute abdomen. A classic experimental study by Miller and Nelson showed that as little as 1 mL of free air can be detected below the right hemidiaphragm on properly exposed upright chest radiographs.⁷⁵ They emphasized the importance of placing the patient in the left lateral decubitus position for 15 to 20 minutes before obtaining a radiograph with the patient in an upright position to maximize the possibility of detecting small amounts of free air. Radiographs obtained in midinspiration or midexpiration are even more likely to reveal subtle findings of pneumoperitoneum.⁷⁶ Chest radiographs obtained with the patient in an upright position are ideal for demonstrating free air because the x-ray beam strikes the diaphragms tangentially at their highest point. A posteroanterior view is usually obtained, but a lateral view of the chest may be even more sensitive.⁷⁷ Although properly performed upright chest radiographs are extremely sensitive for detecting pneumoperitoneum, abdominal CT has been shown to be even more sensitive for detecting tiny amounts of free air in patients with acute trauma.⁷⁸

In contrast, upright abdominal radiographs result in an oblique view of the hemidiaphragms that may obscure free air because the x-ray beam is centered more inferiorly. Left lateral decubitus views of the abdomen are better for detecting small amounts of free air interposed between the free edge of the liver and lateral wall of the peritoneal cavity. Care should be taken to include the upper abdomen, because air rises to the highest point in the abdomen, which frequently is beneath the lower ribs. Radiographs obtained with the patient in the right lateral decubitus position can also be helpful, but gas in the stomach or colon may obscure small amounts of free air. A cross-table lateral view of the abdomen with the patient in a supine position may demonstrate free air in those who are physically unable to roll onto their sides. Not surprisingly, CT also is more sensitive in detecting free air than left lateral decubitus radiographs.⁷⁹

Upright or left lateral decubitus abdominal radiographs are based on the principle that air rises to the highest point in the peritoneal cavity. If, however, horizontal beam views cannot be obtained in patients who are too sick or debilitated to stand or lie on their side, the radiologist must be able to recognize indirect signs of free intraperitoneal air on supine abdominal radiographs. In one study, one or more signs of pneumoperitoneum were present on these radiographs in 59% of patients.⁸⁰

MAJOR SIGNS OF FREE AIR

Major signs of free air on supine abdominal radiographs include the following:

Rigler's Sign. Gas normally outlines only the luminal surface of the bowel. Gas on both sides of the bowel, however, may outline the bowel wall as a thin linear stripe (Fig. 12-10A). Since its original description by Rigler in 1941,⁸¹ this sign has been recognized as an important finding of pneumoperitoneum, but a moderate amount of free air must be present in the abdomen. Extraluminal air trapped between adjacent loops of bowel may also have a characteristic triangular appearance in patients with pneumoperitoneum (Fig. 12-10B). Overlapping loops of small bowel in the central abdomen can mimic Rigler's sign, so it is helpful to evaluate the periphery of the radiograph. A pseudo-Rigler's sign may also result from Mach bands, a phenomenon in which there is the perception of a line at the interface between two areas of differing density (e.g., gas and soft tissue). However, the perceived line has almost no discernable thickness, whereas the bowel wall has a measurable thickness of 1 mm or more in patients with a true Rigler's sign.⁸⁰ Still other patients may have a pseudo-Rigler's sign caused by faint residual oral contrast material (usually from recent abdominal CT) coating the luminal surface of the bowel, so the increased density of the wall creates the erroneous impression that gas is present on both sides of the wall.

Increased Lucency in the Right Upper Quadrant. Air accumulating superiorly in the free space between the anterior aspect of the liver and the abdominal wall may cause increased lucency in the right upper quadrant (Fig. 12-11A). Depending on the habitus of the patient, the lateral border of the air collection may be linear. Small collections of air may be seen as subtle rounded lucencies overlying the liver.⁸² Linear collections of gas may also be seen in the subhepatic space, although the latter finding must be differentiated from subhepatic fat.⁸⁰

Visualization of the Undersurface of the Diaphragm. Air may be trapped anteriorly in the cupola of the diaphragm, permitting visualization of the undersurface of the central portion of the diaphragm or diaphragmatic muscle slips laterally. These findings depend on the amount of air present and on the orientation of the diaphragm.^{83,84}

Air in Morison's Pouch (Posterior Hepatorenal Space). Morison's pouch is an intraperitoneal recess bounded anteriorly by the liver and posteriorly by the right kidney. In the supine position, fluid may gravitate to this space. Air escaping from a perforated viscus may become loculated in this space because of surrounding inflammation. Air in Morison's pouch is characterized radiographically by a linear or triangular collection of gas in the medial aspect of the right upper quadrant outside the expected location of the bowel (Fig. 12-11B).⁸⁵⁻⁸⁷ The gallbladder may also be visualized.⁸⁸

Outline of the Normal Peritoneal Ligaments. Larger amounts of free air may occasionally outline the falciform ligament (Fig. 12-11C) or extrahepatic segment of the ligamentum teres in the right upper quadrant, the lateral umbilical ligaments (inverted V sign) in the lower abdomen, and the urachus.⁸⁹⁻⁹²

Football Sign. Originally described by Miller in infants, this sign is caused by a large amount of free air filling the oval-shaped peritoneal cavity, resembling an American football.⁹³ Occasionally, this sign may be seen in adults.

Air in the Lesser Sac of the Peritoneal Cavity. Intraperitoneal air that traverses the foramen of Winslow may become trapped in the lesser sac. Such gas may be manifested by an ill-defined lucency above the lesser curvature of the stomach.⁹⁴

The presence of pneumoperitoneum does not always indicate an acute abdominal condition. Various causes of free air are listed in Table 12-1.

Pneumoretroperitoneum

Gas that enters the retroperitoneal spaces (also known as pneumoretroperitoneum) can usually be distinguished from intraperitoneal gas. Because retroperitoneal gas is bound by fascial planes, it tends to collect in a linear fashion along the margins of the kidneys and psoas muscles and along the medial undersurface of the diaphragms (Fig. 12-12). Meyers has described the various pathways in which retroperitoneal gas can travel.⁹⁵ Perforation of the retroperitoneal portions of the intestines, such as the duodenum, ascending and descending colon, and rectum, usually accounts for this finding. In patients with sigmoid diverticulitis, gas can extend laterally along the left margin of the psoas muscle or, if the perforation involves the

Pelvic examination
Athletic activities such as water skiing

root of the sigmoid mesocolon, along both margins of the psoas muscle.

The location of retroperitoneal gas may provide a clue to its site of origin. Gas escaping from duodenal perforations tends to be confined to the right anterior pararenal space. Gas may also extend medially across the anterior aspect of the psoas muscle, sparing its lateral margin. Less commonly, gas may enter the perirenal space and outline the right kidney. Duodenal ulcers, iatrogenic duodenal injuries, and blunt abdominal trauma are all possible causes of perforation of the extraperitoneal portion of the duodenum.⁹⁶

Gas from a rectal perforation may be confined to the perirectal space or may extend into the anterior and posterior retroperitoneal spaces and even superiorly into the mediastinum.⁹⁷ Iatrogenic trauma is a common cause of rectal perforation. Radiologists should always be aware of the potential risk of rectal perforation when insufflating a balloon during barium enemas.⁹⁸

Pneumobilia

Gas in the bile ducts, or *pneumobilia*, is characterized radiographically by thin, branching, tubular areas of lucency in the

Figure 12-12 Retroperitoneal air in a patient with retroperitoneal perforation after endoscopy. **A.** Retroperitoneal air is manifested by linear gas collections (arrows) dissecting along the right margin of the psoas muscle in the upper retroperitoneum to the undersurface of the medial aspect of the right hemidiaphragm. **B.** CT confirms the retroperitoneal location of this extraluminal air (arrows). (Courtesy Laura R. Carucci, MD, Richmond, VA.)

Figure 12-13 Pneumobilia. Air is seen collecting centrally in the biliary tree (arrows) in a patient who had a choledochojejunostomy.

central portion of the liver (Fig. 12-13). This central location is explained by the flow of bile from the periphery of the liver toward the porta hepatis.

Pneumobilia almost always results from some type of communication between the bile ducts and intestine. One of the most common causes is a surgically created biliary enteric fistula such as a choledochojejunostomy or cholecystojejunostomy (see Fig. 12-13). The most common nonsurgical cause of a choledochoduodenal fistula is a penetrating duodenal ulcer,⁹⁹ and the most common nonsurgical cause of a cholecystoduodenal fistula is a gallstone eroding into the duodenum. In some patients with a cholecystoduodenal fistula, a patent cystic duct may allow air to enter the intrahepatic bile ducts.^{100,101} If the ectopic gallstone is 2.5 cm or larger in diameter, it may obstruct the small bowel, usually at or near the ileocecal valve, and produce a so-called gallstone ileus; this is actually a misnomer because these patients have mechanical small bowel obstruction caused by a gallstone impacted in the distal ileum. The classic

triad (also known as Rigler's triad) of air in the biliary tree, small bowel obstruction, and an ectopic calcified gallstone is almost diagnostic of gallstone ileus on abdominal radiographs.¹⁰² An incompetent sphincter of Oddi, recent sphincterotomy or sphincteroplasty, anomalous insertions of the biliary tree, recent passage of a common duct stone, and infestation of the biliary tract by *Ascaris* are other causes of pneumobilia.^{103,104}

The radiographic appearance of pneumobilia is sufficiently characteristic to allow a confident diagnosis on the basis of the findings on abdominal radiographs. Occasionally, periportal fat or fat around the ligamentum teres hepatis may be manifested by a faint lucency over the liver, but its appearance is different from that of pneumobilia.^{105,106} The most important consideration in the differential diagnosis of pneumobilia is the presence of gas in the portal venous system (see later, "Portal Venous Gas").

Portal Venous Gas

Portal venous gas was originally described in adults by Susman and Senturia in 1960.¹⁰⁷ This ominous radiographic finding is manifested by thin, branching, tubular areas of lucency that occupy the periphery of the liver and extend almost to the liver surface (Fig. 12-14). The peripheral location of the gas reflects the hepatopetal flow of blood in the portal venous system away from the porta hepatis. In advanced cases, air can be seen outlining the more centrally located main portal vein, but this finding is less common. A left lateral decubitus radiograph of the abdomen may facilitate visualization of portal venous gas. Unless the gas has been introduced iatrogenically by vascular catheterization, endoscopic manipulation, or other iatrogenic causes, the source of the gas is almost invariably the intestine. Intraluminal intestinal air can breach a damaged mucosa, enter the bloodstream, and eventually reach the portal venous system of the liver.

The most important cause of portal venous gas is intestinal ischemia or infarction. In adults with ischemic bowel disease, death often occurs shortly after portal venous gas has been observed.^{108,109} The finding of portal venous gas should therefore lead to a careful search for gas in the wall of the bowel caused by intestinal infarction (see later, "Intramural Gas").

Portal venous gas may occasionally have benign causes. Dilation of the stomach and small bowel may allow air to enter the

Figure 12-14 Portal venous gas. Tiny, branching gas collections (arrows) are seen extending toward the periphery of the liver.

intestinal mucosa, eventually reaching the liver.¹¹⁰ Nonfatal cases of portal venous gas have also been described in patients with diverticulitis and inflammatory bowel disease and in patients who have undergone a double-contrast barium enema or colonoscopy for inflammatory bowel disease.¹¹¹⁻¹¹⁴ Traumatic injury to the common bile duct as a complication of endoscopic retrograde cholangiopancreatography (ERCP) and endoscopic sphincterotomy has also been reported as a benign cause of portal venous gas.¹¹⁵ Portal venous gas has even been described as a transient finding on Doppler ultrasound during the early postoperative period after liver transplantation.¹¹⁶

Hepatic Arterial Gas

Gas in the hepatic artery has been reported anecdotally in a patient in whom the hepatic artery was ligated for the treatment of an unresectable hepatic adenoma.¹¹⁷ The smaller caliber of the hepatic artery and relative paucity of intrahepatic branches should differentiate this finding from portal venous gas. Hepatic arterial gas may be reported more frequently as the use of aggressive interventional radiographic techniques increases for the treatment of hepatic neoplasms.

Intramural Gas (Pneumatosis)

Gastric emphysema is a relatively benign form of pneumatosis usually resulting from iatrogenic injury to the mucosa at endoscopy or increased intraluminal pressure in the stomach associated with gastric outlet obstruction.^{118,119} This condition is characterized by linear collections of gas in the wall or stomach. In contrast, emphysematous gastritis is a rare fulminant variant of phlegmonous gastritis; hemolytic *Streptococcus* is the most commonly implicated organism.^{120,121} Underlying causes of this life-threatening condition include ingestion of caustic substances, severe gastroenteritis, and gastroduodenal surgery that

Figure 12-15 Infarcted bowel with intramural gas. Linear gas collections (arrows) are seen in the wall of several dilated small bowel loops in a patient with bowel infarction.

compromises the vascular supply of the stomach.^{120,121} Emphysematous gastritis is characterized by cystic, bubbly collections of gas in the gastric wall that have a very different appearance than that of the linear intramural collections seen in gastric emphysema.

Gas in the wall of the small bowel, which is termed *pneumatosis intestinalis*, is characterized by two radiographic patterns—a bubbly appearance or thin, linear streaks of gas.¹²² The bubbly appearance of intramural gas is easily mimicked by fecal material within the colon. In patients with this form of pneumatosis, close inspection may reveal small bubbles of gas outside the confines of the bowel, leading to the correct diagnosis. In contrast, linear gas collections tend to be more readily apparent and should always be considered an important finding on abdominal radiographs, regardless of their location (Fig. 12-15). In combination with portal venous gas (see earlier, “Portal Venous Gas”), linear gas collections in the intestinal wall are almost always a sign of bowel infarction in adult patients.¹²³ Other findings of bowel ischemia or infarction on abdominal radiographs include dilation of bowel and nodular thickening or thumbprinting of the bowel wall. CT may also reveal characteristic findings in patients with bowel ischemia or infarction.^{124,125} Pneumatosis is particularly well shown by CT, but does not always indicate infarction of the bowel unless the pneumatosis is associated with portomesenteric venous gas.¹²⁶ The linear pattern of pneumatosis identified on CT is more likely to be associated with transmural bowel infarction than the bubbly pattern.¹²⁷

Pneumatosis cystoides intestinalis and pneumatosis coli are rare benign conditions characterized by multiple gas-filled cysts or blebs in the wall of the small bowel and colon, respectively. The cysts appear radiographically as grapelike clusters of gas, usually segmental in distribution (Fig. 12-16). These cystic collections may protrude into the bowel lumen, giving the small

bowel or colon a scalloped appearance on barium studies. In the large intestine, the left colon tends to be involved more frequently than the right colon. Despite the dramatic radiographic findings, affected individuals may have mild abdominal pain or may even be asymptomatic. The cysts often resolve spontaneously, but oxygen inhalation therapy has been used to facilitate resolution of these lesions.¹²⁸⁻¹³⁰

Figure 12-16 Pneumatosis coli. Multiple rounded, grapelike collections of gas (arrows) are seen in the wall of the sigmoid colon in a patient with benign pneumatosis coli.

Abscesses

Although CT is the most definitive radiologic test for diagnosing abscesses, abdominal radiographs may also be helpful for these patients.^{120,131,132} An abscess may be manifested by an extraluminal soft tissue mass that displaces adjacent bowel or by an extraluminal collection of gas. The most characteristic finding on abdominal radiographs is a mottled or bubbly gas collection within the abscess (Fig. 12-17A). Other patients may have a single rounded or ovoid collection of gas with an air-fluid level on horizontal beam views. Fecal material can mimic the appearance of a mottled gas collection but usually is distinguished by its location within the colon. A gastric or small bowel bezoar can also mimic an abscess.

Infections of any intra-abdominal or retroperitoneal structure can result in the production of gas. Correlation of a linear or bubbly gas collection with knowledge of the anatomy is usually sufficient to localize the structure involved. The abdominal radiograph may be the initial study to suggest a gas-forming process, but CT is generally more useful in assessing the extent of disease and cause of the underlying pathology (Fig. 12-17B).¹³³

Normal Soft Tissue Structures

The ability to discern the edge of intra-abdominal organs on abdominal radiographs obtained with the patient in a supine position depends on the differences in x-ray attenuation between water density, fat density, and air. Intraperitoneal and retroperitoneal fat are present in varying degrees in even the thinnest patients. The liver, spleen, kidneys, psoas muscles, and urinary bladder can often be readily demonstrated because of surrounding fat (Fig. 12-18). In patients with sufficient fat, the serosal surface of the stomach may also appear as a faint edge. This subtle radiographic observation should not be confused with the much more distinct appearance of the serosa when it is outlined by air in patients with pneumoperitoneum. Fluid-filled loops of small and large bowel may also appear as tubular densities on a backdrop of abdominal fat. Recognition of organs is important because an abnormal contour or size of these organs may be the first indication of intra-abdominal disease.

Figure 12-17 Lesser sac abscess secondary to pancreatitis. **A.** A mottled collection of gas (arrows) is present in the left upper abdomen. **B.** CT shows gas and fluid (arrows) in the abscess cavity in a patient with pancreatitis.

Soft Tissue Abnormalities

LIVER

Liver size was estimated on abdominal radiographs by Pfahler as early as 1926.¹³⁴ Measurements of the liver on upright abdominal radiographs have been found to be reliable in detecting hepatomegaly.¹³⁵ The inferior tip of the liver usually does not extend below the iliac crest, except in asthenic individuals. Generalized hepatic enlargement tends to displace the hepatic flexure and transverse colon inferiorly and the stomach to the left (Fig. 12-19). Other signs of hepatic enlargement include the following: (1) extension of the inferior edge of the liver beyond

Figure 12-18 Normal soft tissue planes outlined by fat. The liver edge (large white arrows), left renal outline (small white arrows), margins of the psoas muscles (small black arrows), and splenic tip (large black arrow) can be identified.

the right margin of the psoas muscle; (2) displacement of the duodenal bulb below the L2 vertebral body or to the left of the midline; (3) inferior displacement of the right kidney; (4) enlargement or marked rounding of the hepatic angle; (5) elevation of the right hemidiaphragm, with decreased motion on respiration; (6) inferior or lateral displacement of the stomach with left lobe enlargement; and (7) anterior displacement of the duodenal bulb on lateral radiographs with caudate lobe enlargement.¹³⁶⁻¹³⁹ A small liver may result in reversal of some of these findings, with the right kidney higher than the left, the stomach displaced upward and to the right, and the duodenal bulb displaced above the level of the right 12th rib.

SPLEEN

Brogdon and Cros have found that the inferior tip of the spleen can be seen on abdominal radiographs in 44% of patients who had no evidence of splenomegaly.¹⁴⁰ The superior margin of the spleen normally lies just beneath the left hemidiaphragm, and its lateral edge approximates the lateral abdominal wall. As the spleen increases in size, its tip extends inferiorly below the 12th rib (Fig. 12-20). Displacement of the splenic flexure of the colon is an uncommon finding because the splenic flexure usually lies anterior to the spleen. A markedly enlarged spleen may also displace the stomach medially and anteriorly.

KIDNEYS

Because of surrounding fat, the renal outlines are visible on most abdominal radiographs. Moel studied 100 men and 100 women from 20 to 49 years of age and found that the average renal length on abdominal radiographs was 13.0 cm for men and 12.5 cm for women.¹⁴¹ Estimates of renal size must also take into account the foreshortening of the kidney that occurs because of angulation of this structure in normal individuals. Because of its retroperitoneal location, an enlarged kidney does not displace intra-abdominal organs, except in extreme cases. Renal cysts or tumors that produce contour abnormalities in the kidney may be readily apparent.

Figure 12-19 Hepatomegaly. **A.** Marked hepatic enlargement causes increased soft tissue density over the upper abdomen and displacement of bowel inferiorly. **B.** CT confirms hepatomegaly with multiple large metastases in the liver.

OTHER STRUCTURES

Retroperitoneal fat and intraperitoneal fat that permit visualization of adjacent water-density organs are helpful for evaluating contiguous pathologic processes in the abdomen. Surrounding inflammation may cause the fat to become edematous, so it takes in more water and approximates soft tissue density, thus obliterating contiguous planes. These changes are exemplified in patients with appendicitis because the normal margin of the psoas muscle and properitoneal fat planes demarcating the

Figure 12-20 Splenomegaly. Supine abdominal radiograph shows marked splenic enlargement (arrows) with displacement of bowel inferiorly.

internal oblique, external oblique, and transversalis muscles of the abdomen may be obliterated. Although loss of these fat planes is an important sign of inflammation, it seldom occurs as an isolated finding, so it should be interpreted with caution and in conjunction with other signs of abdominal disease.

ASCITES

Because of the widespread use of abdominal CT and ultrasound, less emphasis is now placed on the findings of ascites on abdominal radiographs. It is still important to recognize these signs, however, because abdominal radiography is frequently one of the first imaging studies performed in patients with abdominal distention. In general, only large amounts of ascites can be identified on abdominal radiographs (Fig. 12-21).

Major Signs of Ascites

Major signs of ascites on abdominal radiographs include the following:

Obliteration of the Inferior Edge of the Liver. This sign can be extremely helpful (see Fig. 12-21A). Proper technique with the use of low kilovoltage is essential. The liver edge may be preserved in patients with loculated ascites, and excessive feces in the hepatic flexure of the colon may falsely obliterate the liver edge.¹⁴²

Widening of the Distance Between the Flank Stripe and Ascending Colon. This distance is normally 2 to 3 mm, but may increase as fluid fills the right paracolic gutter.

Medial Displacement of the Lateral Edge of the Liver (Hellmer's Sign). This finding usually requires a large amount of ascites and is more common with malignant ascites than with cirrhosis, probably because the fat content of the cirrhotic liver approximates the density of ascites.¹⁴³

Fluid Accumulation in the Pelvis. Intraperitoneal fluid tends to accumulate in the most inferior intraperitoneal recess, also known as the pouch of Douglas or cul de sac. A distended

Figure 12-21 Ascites. A. The normal liver edge is obscured. The bowel loops are centrally located in the abdomen, and there is separation of bowel loops. **B.** CT confirms the presence of perihepatic ascites.

bladder or rectum may impress centrally on this fluid, causing symmetric bulges that have been described as dog ears.

Separation of Bowel Loops. This sign is seldom seen as an isolated finding and requires a large amount of ascites (see Fig. 12-21A). It can easily be mimicked by a disproportionately large amount of fluid and smaller amount of air in juxtaposed bowel loops.

Centrally Located Bowel Loops with Bulging Flanks. With large amounts of ascites, bowel loops may float to the most nondependent central portion of the abdomen (see Fig. 12-21A).

Ground-Glass Appearance. This radiographic finding also requires large amounts of fluid and may erroneously be suggested by improper radiographic technique or marked obesity.

Abdominal Calcifications

STEPHEN R. BAKER

CHAPTER OUTLINE

Physiology

Morphology

Concretions

Conduit Wall Calcification

Cystic Calcification

Solid Mass Calcification

Difficulty in Classification

Location

Mobility

The abdomen is a closely packed space containing numerous conduits and organs related to each other in a complex spatial arrangement. Each of these structures is subject to a unique range of diseases, all having specific causes and characteristic manifestations. However, the spectrum of findings on abdominal radiographs is surprisingly limited. Important signs include displacement, enlargement, or atrophy of organs, distention of bowel, extraluminal gas, and calcification in parenchymal and supporting tissues. In many cases, the pattern of calcium deposition is the most informative and distinctive radiographic finding.

Calcification may occur in the wall of blood vessels or other conduits, the lumen of hollow structures, and the solid substance of viscera or neoplasms. Despite the variety of causes of abdominal calcification, a systematic evaluation of the morphologic features, location, and mobility of an abnormal opacity usually narrows the diagnostic considerations to just a few likely possibilities. In many cases, analysis of the appearance of an abdominal calcification on abdominal radiographs provides sufficient information for an unequivocal diagnosis without need for additional examinations. In other cases, careful assessment of the morphology, location, and mobility of an abdominal calcification helps focus the choice and sequence of subsequent imaging examinations.

Physiology

The precipitation of calcareous substances requires an alkaline medium and high local concentrations of ionic calcium. The term *metastatic calcification* refers to the deposition of calcium salts in normal tissues as the result of hypercalcemia and an elevated pH. Although the stomach and kidneys are the most frequent sites of metastatic calcification in the abdomen, the degree of parenchymal opacification in these organs is usually too faint to be detected on abdominal radiographs. The most common cause of radiographically detectable metastatic calcification is chronic renal failure with secondary

hyperparathyroidism.¹ As a result of this pathologic process, diffuse opacification of the kidneys is often accompanied by osteomalacia or osteoporosis.

The term *dystrophic calcification* refers to a phenomenon, far more frequent than metastatic calcification, that occurs despite normal serum levels of calcium. Dystrophic calcification may be caused by trauma, ischemia, infarction, or other pathologic processes, resulting in a predisposition to calcium deposition. In some tumors, the rapid breakdown of lipids releases fatty acids that bind calcium with particular avidity. Mucin-producing adenocarcinomas of the gastrointestinal (GI) tract possess a glycoprotein similar in chemical configuration to cartilage and share with it an affinity for calcium aggregation.² Although some structures in the abdomen have a propensity for dystrophic calcification, the mechanisms and kinetics of calcium deposition have not been fully elucidated.

Some devitalized or degenerative tissues are also associated with new bone formation. However, ossification is less common than dystrophic calcification. Calcified osteoid may be found as an isolated finding, or it may coexist with adjacent areas of calcium deposition that lack the histologic structure of bone. In either case, local tissue damage appears to be the precipitating factor. Ossification may occur in ovarian or retroperitoneal teratomas (Fig. 13-1), abdominal scars, particularly after gastric surgery or suprapubic bladder catheterization and, rarely, colonic and retroperitoneal neoplasms.

Papillary serous cystadenocarcinomas of the ovary often contain a distinctive form of calcification characterized by a psammomatous or cloudlike opacity attributable to intracellular deposition of calcium salts in the lesion (Fig. 13-2).³ In contrast, dystrophic calcification associated with other metastatic tumors is caused by extracellular precipitation of calcium salts. Psammomatous and dystrophic calcification may be manifested by amorphous, poorly outlined areas of increased density. When this finding occurs, the distribution of calcified metastases may narrow the differential diagnosis, sometimes leading to an unequivocal diagnosis.

Morphology

The recognition of specific abdominal calcifications has been aided by the attribution of vivid descriptive names to particular radiopacities. For example, a “staghorn calculus” is a large, branching opacity in the renal pelvis. Such appellations are highly evocative and easily remembered; however, they do not help generate a differential diagnosis from among the many causes of abdominal calcification. Unfortunately, most surveys of abdominal calcification have relied primarily on such descriptive designations and have failed to emphasize diagnostic features that might help organize the various opacities into categories with shared characteristics.

In this chapter, a logical scheme is presented for classifying almost all abdominal calcifications. They may be distinguished radiographically on the basis of various morphologic features, including contour, border, sharpness, marginal continuity, and internal architecture. Consideration of these features permits a grouping of calcifications into one of four classes: (1) concre-

Figure 13-1 Retroperitoneal teratoma. Both teeth (*arrows*) and bone (*arrowhead*) are visualized. Note the cortex and trabecula in the disordered pattern of ossification.

Figure 13-2 Ovarian papillary serous cystadenocarcinoma. Patches of psammomatous calcification (*arrow*) are seen in the left abdomen in an intraperitoneal metastasis.

tions; (2) conduit wall calcification; (3) cystic calcification; and (4) solid mass calcification. In the following sections, the distinguishing features of each class are discussed in detail. Potential pitfalls and notable exceptions are also considered.

CONCRETIONS

Concretions are precipitates removed from solution in a liquid medium inside a vessel or hollow viscus. They often contain a central nidus, composed of an insoluble substance such as an inorganic foreign body, ingested vegetable matter, thrombus, or focal collection of pus and cellular debris. In pelvic veins and in the GI and genitourinary tracts, concretions are likely to calcify. They can be brightly or faintly opaque; the radiographic density depends on the size of the opacity and amount of calcium per unit volume. Concretions do not have a common shape. Biliary calculi are usually oval or rounded, whereas gallstones are often faceted (*Fig. 13-3*). Ureteral and pancreatic stones often have jagged edges, but in hollow viscera such as the urinary bladder and gallbladder, the concretions usually have smooth margins.

A sharply defined, continuous external margin is a unifying feature of concretions. Stones are almost always characterized by an uninterrupted edge of calcification throughout their entire perimeter, with no lucent gaps along the interface with the surrounding medium. This unique feature permits

Figure 13-3 Biliary stones. Numerous stones are seen in the gallbladder (*straight white arrow*), cystic duct (*black arrow*), and common bile duct (*curved white arrow*). Note how the stones have faceted margins.

Figure 13-4 Ovarian vein phleboliths. Numerous phleboliths, each having a central lucency, are located within a dilated right ovarian vein.

differentiation of small stones with radiolucent centers from calcified vessels seen on end. The circumferential opacification of the perimeter of large stones also helps distinguish them from calcified cysts.

Concretions may vary greatly in their internal architecture. A stone may be homogeneously dense, a pattern often encountered in urinary calculi, or it may contain a slightly eccentric area of lucency, an appearance typical of phleboliths (Fig. 13-4). Concentric laminations are characteristic of gallstones, bladder concretions, and appendicoliths (Fig. 13-5). Each of these various internal configurations has a certain predictability and uniformity. A central lucency is often present. Stones seldom have a mottled, speckled, or patchy appearance. The deposition of calcium on only one surface of the stone is extremely rare.

Unlike calcified solid lesions or cysts, which are pathologic tumefactions that distort or displace normal organs and supporting structures, stones tend to be confined within preexisting vessels or fluid-filled viscera. When multiple stones are present, they may outline the course of a hollow tube or the dimensions of a distensible reservoir. Concretions appearing outside expected anatomic locations are unusual, such as multiple phleboliths in a hemangioma, ectopic gallstones in the distal small bowel in a patient with gallstone ileus, and appendicoliths from a ruptured appendix in the peritoneal cavity.

CONDUIT WALL CALCIFICATION

Conduits are fluid-conducting hollow tubes. In the abdomen, they include the ureter, urethra, vas deferens, pancreatic ducts, bile ducts, and vascular structures. The vast majority of

Figure 13-5 Lamellated appendicolith. Note the continuous margin of calcification, parallel lamina, and small medial bulge along the edge of this concretion.

Figure 13-6 Conduit wall calcification in the vas deferens. Marginal opacities are seen en face and in profile.

conduit wall calcifications are located in the aorta and its branches. The tubular configuration characteristic of conduits is readily appreciated if the calcification is extensive and circumferential. When the vessel is parallel to the radiographic beam, a ringlike density is often observed (Fig. 13-6). In contrast to calculi, conduit wall calcifications often have gaps in the opaque ring. Because calcification in conduit walls is not uniform, alternating radiopaque and radiolucent areas may be seen along the course of the vessel. Internal radiopacities are not a feature of conduit wall calcifications, so

Figure 13-7 Calcification of the renal arteries and their intrarenal branches. These opacities have the typical configuration of conduit wall calcification.

the presence of central radiopaque areas brighter than the periphery of the agglomeration of a radiodensity should suggest another class of abdominal calcifications. Even when there is profuse mural calcification, the lateral walls of the conduit provide a longer path for the x-ray beam to traverse than the anterior or posterior walls, so they appear more opaque than the vessel wall oriented en face. As a result, a conduit wall calcification is usually manifest by parallel linear opacities when the vessel is aligned along the course of the x-ray beam or by a circle of radiopacity when the beam is directed perpendicular to the course of the conduit. A marginal branching pattern may be observed at the bifurcation of the abdominal aorta or in the intrarenal arteries (Fig. 13-7). Calcification of narrow-caliber vessels occasionally produces a stringlike appearance. In the female pelvis, calcification of the uterine artery may be evident by a horizontal or slightly undulating linear opacity or by a series of curvilinear stringlike densities.

Conduit wall calcification is clearly distinguishable only if deposition of calcium is extensive. A single fleck of calcification can simulate a small calculus or even a thin piece of cortical bone, particularly in the renal pelvis. Conversely, the lateral margin of the transverse process of a lumbar vertebra can mimic calcification in the renal artery. However, the lateral margin of the transverse process has a vertical orientation, whereas the renal artery is oriented horizontally (see Fig. 13-7).

Conduit wall calcification is usually found at the expected location of vessels. Thus, it is not seen at the lateral margin of the spleen or in other peripheral locations. As arteries become tortuous and dilated, however, their walls may eventually be displaced several centimeters or more from their expected location. Hence, the wall of a dilated calcified aorta may be seen to overlie the midline, or even to lie to the right of the spine on abdominal radiographs.

CYSTIC CALCIFICATION

Cystic calcification is characterized by the deposition of calcium in the wall of abnormal fluid-filled masses, a category encompassing true epithelial cysts, pseudocysts, and aneurysmally dilated arteries. Despite the diversity of cystic structures in the abdomen, cystic calcification exhibits remarkably uniform radiographic findings.

A cystic pattern of calcification is characterized by the presence of a smooth arcuate rim of radiopacity in the wall of the cyst (Fig. 13-8). Although opacities may be present in cysts and

Figure 13-8 Large echinococcus cyst in the liver. Note how the calcified wall of the cyst is flattened inferiorly.

conduits, the calcified rims of almost all cysts have a larger diameter than those of most conduits. Unlike stones, this calcified rim is often incomplete, and in many cases only a small section of the wall contains radiographically visible calcium. Moreover, morphologically uncomplicated cysts have only a single encircling wall, so when calcified, they do not have a laminated appearance. Cysts need not be perfectly round; some can be compressed on one side, producing an ovoid configuration (see Fig. 13-8).

The configuration of cysts depends on their location. They may displace and distort adjacent structures, or they themselves may be displaced by nearby solid organs or vessels. Usually, the differentiation of cystic calcification from the diffuse opacification of solid masses is not difficult. Nevertheless, solid uterine leiomyomas may contain curvilinear calcifications at their margins, mimicking the appearance of cystic calcification.

Unlike concretions and conduit wall calcifications, which appear at expected locations, the cystic pattern of calcification may be found almost anywhere in the abdomen. Cystic calcification usually occurs in abdominal aortic aneurysms. It is generally associated with conduit wall calcification in contiguous sections of the aorta and in the common iliac arteries. Cystic calcification may also occur in aneurysms of the splenic artery in the left upper quadrant. Also, cystic calcification is encountered in a variety of urinary tract lesions, including aneurysms of the renal artery, echinococcus cysts, perirenal hematomas, multicystic kidneys, adrenal cysts, and renal carcinomas. Echinococcal cysts are the most common cause of cystic calcification in the liver, but a calcified gallbladder (i.e., a so-called porcelain gallbladder) may occasionally produce similar findings.¹ Other causes of cystic calcification in the lower abdomen include mesenteric cysts, calcified appendiceal mucocoeles, and calcified benign tumors of the ovary.

SOLID MASS CALCIFICATION

Of all the classes of abdominal calcification, solid mass calcification includes the greatest variety of pathologic

Figure 13-9 Calcified mesenteric nodes. Mottled interior and slightly irregular margins are typical of lymph node calcification.

Figure 13-10 Calcified uterine leiomyomas. Two uterine fibroids are manifested by poorly defined, flocculent calcifications admixed with irregular lucencies.

abnormalities. Solid masses may appear as mottled densities with scattered radiolucencies on a calcified background, an appearance typical of calcified mesenteric lymph nodes (Fig. 13-9). A whorled configuration with incomplete bands and arcs of calcification is a feature of uterine leiomyomas. Calcified leiomyomas may also be manifested by numerous flocculent densities superimposed on a radiolucent background. Solid calcifications share the unifying feature of a nongeometric inner architecture and an irregular, often incomplete margin.

Calcified solid masses can be located anywhere in the abdomen. Calcified mesenteric lymph nodes are usually found in middle-aged or older individuals who at one time in life were infected by tuberculosis, even if they are now purified protein derivative–negative and exhibit no other manifestations of the disease. They tend to be located in a broad arc along the course of the mesentery of the small bowel from the left upper quadrant to the right lower quadrant of the abdomen. Multiple calcified nodes are often present, and individual nodes may vary widely in diameter.

Uterine leiomyomas are the most common calcified solid masses in the female pelvis. Some patients have multiple leiomyomas that may become calcified as they grow to enormous sizes (Fig. 13-10). Although leiomyomas are usually located in the pelvis, they may occasionally be found almost anywhere in the abdomen (Fig. 13-11).

All other types of solid mass calcification are much less common than calcified mesenteric lymph nodes or calcified uterine leiomyomas. A solid pattern of calcification may occasionally be found in adenomas, hamartomas, and carcinomas of the kidney as well as in tuberculous and chronic pyogenic abscesses of the kidney. Calcified pancreatic masses are rare and are usually associated with benign or malignant cystadenomas. Small, discretely outlined, calcified densities in the liver and spleen usually represent granulomas. In contradistinction, poorly defined radiopaque areas in the liver should be considered an indication of calcified metastases from colonic carcinoma until proven otherwise.

Figure 13-11 Multiple calcified leiomyomas. This patient has different patterns of calcification in leiomyomas extending from the pelvis to the midabdomen.

DIFFICULTY IN CLASSIFICATION

This classification scheme can be applied broadly to determine the nature of most abdominal calcifications. However, some cannot be separated into one of the four classes. If the density is too faint to have a definite inner architecture or margin, morphologic analysis is not possible. In addition, if the calcification is extremely small, a concretion may be

Figure 13-12 Two calcification patterns in pancreatic lithiasis. **A.** A conglomerate of stones filling larger ducts in the pancreatic head could be mistaken for calcification in conduits. **B.** Pancreatic stones can be seen throughout the pancreas. Each stone is located within a duct, but the cumulative appearance suggests diffuse acinar opacification.

difficult to distinguish from a solid opacity. Other calcifications may have an appearance suggestive of more than one morphologic class. For example, a collection of pancreatic stones clustered together may resemble a solid mass, although the area of radiopacity actually represents innumerable intra-ductal concretions with irregular margins (Fig. 13-12). Thus, one must be aware of potential pitfalls in the classification of abdominal calcifications. Nevertheless, a specific abdominal calcification can usually be classified into one of the four morphologic categories with a reasonable degree of confidence.

Location

The location of abdominal radiopacities also provides important clues about their identity. Most calcifications in the right upper quadrant are related to the gallbladder or right kidney. Gallstones are often multiple and are frequently laminated. Gallbladder wall calcification is much less common but can be clearly recognized by its marginal arcuate configuration. A transverse orientation and conduit morphologic features indicate calcification of the renal artery. Stones in the renal pelvis and ureters have a range of specific appearances and are oriented along the course of the urinary tract.

In both upper quadrants, adrenal calcification may assume various forms, including the solid opacities of calcified granulomas and eggshell calcification of cysts and pheochromocytomas. Multiple calcifications crossing the midline of the upper abdomen are characteristic of pancreatic lithiasis. Calcified mesenteric lymph nodes may also cross the midline but are usually situated more inferiorly along an oblique path extending from the left midabdomen to the right lower quadrant.

Appendicoliths typically appear as a single or tight grouping of several laminated calcifications in the right lower quadrant. However, the appendix may be located anywhere between the lower pelvis and right upper quadrant, so the diagnosis of an appendicolith should not be excluded simply because the concretion is found at a considerable distance from its expected location in the right iliac fossa.

In the lower abdomen and pelvis, calcifications that appear as concretions should arouse suspicion of ureteral calculi;

however, a small ureteral stone is often difficult to distinguish from a phlebolith on a single radiograph. Reference should therefore be made to previous or subsequent radiographs. Calculi may move freely within the ureteral lumen, whereas pelvic phleboliths are fixed in position unless displaced by an enlarging extraperitoneal mass. Bladder stones are usually readily recognizable by their location and configuration. Because of their protean manifestations, however, calcified uterine leiomyomas may be confused with other calcified lesions in the pelvis, such as ovarian tumors and mesenteric lymph nodes. Cystic teratomas of the ovary can frequently be recognized by the presence of teeth and bone, which are often accompanied by a large homogeneous lucency, indicating fat within the tumor.

Mobility

The movement of abdominal calcifications, during a single examination or over a longer period, provides additional information that may lead to a specific diagnosis. Gravity, respiration, peristaltic activity, and growth of masses may all result in changes in location. Stones located in a fluid medium may undergo layering on abdominal radiographs obtained in upright or decubitus projections. Such manipulation of position may be helpful in the diagnosis of gallstones or of calculi in hydronephrotic sacs. Epiploic appendices that have become amputated or appendicoliths that lie free in the peritoneal cavity may exhibit a great range of movement on sequential radiographs. Whereas mesenteric nodes move slightly with positional changes, ovarian teratomas may move considerably as the bladder fills and empties (Fig. 13-13). Because of the effects of peristalsis, stones in the lumen of the GI tract and pelviciceal system can migrate on successive radiographs. Consideration of this migration is particularly important in diagnosing ectopic gallstones and in differentiating distal ureteral calculi from stones in pelvic veins (Fig. 13-14). When images are obtained over a period of weeks or months, enlargement or shrinkage of abdominal masses may be recognized by the movement of calcifications or ossifications that lie within or adjacent to these lesions. Even pelvic phleboliths can be displaced by hematomas or other masses.⁴

Figure 13-13 Mobility of ovarian dermoid. **A.** When the bladder is full, the tumor rises into the lower abdomen. **B.** When the bladder has been emptied, the calcified mass overlies the sacrum.

Figure 13-14 Mobility of ureteral calculus. **A.** A phlebolith (arrow) and ureteral calculus (arrowhead) are morphologically identical on the initial abdominal radiograph. **B.** However, the venous stone (arrow) maintains a fixed position, whereas the ureteral stone (arrowhead) has migrated distally on a subsequent radiograph.

Therapeutic Examination

The pharynx is the crossroads of respiration, speech, and swallowing. During respiration, the pharynx is an active conduit for the passage of air from the nasopharynx to the laryngeal aditus. During speech, the pharynx functions as a resonating chamber, changing size and shape to alter sounds. During swallowing, the pharynx directs the bolus into the esophagus and prevents the bolus from entering the tracheobronchial tree. Disorders of the pharynx may therefore be manifested by respiratory, speech, or swallowing dysfunction. Patients may complain of dysphagia, odynophagia, choking, or a feeling of a lump in the throat not associated with swallowing (a globus sensation). Soft palate insufficiency may be suggested by nasal regurgitation or a nasal voice quality. Recurrent pneumonia, asthma, chronic bronchitis, or coughing may indicate pharyngeal dysfunction. In this chapter, the focus is on the anatomy of the pharynx as a basis for understanding structural and motility disorders. The neurologic anatomy necessary for understanding motility disorders is presented in Chapter 15.

Anatomy

LOCATION

The pharynx is a funnel-shaped tube of skeletal muscle extending from the cranial base to the lower margin of the cricoid cartilage (Fig. 14-1). The pharynx lies anterior to the vertebral bodies of the cervical spine, prevertebral muscles, and loose connective tissue of the retropharyngeal space.^{1,2} The pharynx is confined laterally by the muscles of the neck, lateral portions of the hyoid bone and thyroid cartilage, and carotid sheath (Fig. 14-2). The pharynx and larynx are intimately related (Fig 14-3), in embryologic origin and anatomically. The epiglottis and

remainder of the supraglottis are of pharyngeal, not laryngeal origin.

BASIC STRUCTURES AND MUCOSAL SURFACE PATTERNS

The shape of the pharynx is determined by the underlying musculature, laryngeal cartilages, and supporting skeleton.³ Although the nasopharynx is primarily a respiratory tract structure, certain nasopharyngeal structures participate in the act of swallowing. The eustachian tube connects the middle ear with the nasopharynx, allowing equilibration of air pressures on the internal and external aspects of the tympanic membrane during swallowing.⁴ During breathing, however, the eustachian tube is closed. The eustachian tube cartilage bulges into the lateral nasopharyngeal wall at the torus tubarius.⁵ A C-shaped prominence is seen radiographically near the torus tubarius (Fig. 14-4).⁶ The salpingopharyngeal fold overlying the salpingopharyngeal muscle courses inferiorly from the torus along the lateral pharyngeal wall to the level of the soft palate.⁷ The posterior nasopharyngeal wall has a variably nodular surface because of underlying adenoidal tissue.⁸

The vertical (pharyngeal) surface of the base of the tongue is variably nodular because of underlying lymphoid tissue of the lingual tonsil (see Fig. 14-1A).⁹ The median glossoepiglottic fold overlies the glossoepiglottic ligament, which courses from the base of the tongue to the epiglottis. The median glossoepiglottic fold divides the space between the tongue and the epiglottis into two sacs, the valleculae (Fig. 14-5; see Fig. 14-1). The lateral glossoepiglottic folds form the lateral walls of the valleculae. The pharyngoepiglottic folds course from the posterolateral portion of the valleculae into the lateral pharyngeal wall (Fig. 14-6).¹ These folds overlie the paired stylopharyngeal muscles and form the posterior lateral wall of the valleculae. The valleculae are spaces at rest but disappear during swallowing when the epiglottis inverts and the space behind the base of the tongue communicates freely with the remainder of the oropharynx.¹⁰

The tonsillar fossa forms part of the lateral oropharyngeal wall. Each tonsillar fossa is bounded anteriorly by a palatoglossal fold (anterior tonsillar pillar; Fig. 14-7) and posteriorly by a palatopharyngeal fold (posterior tonsillar pillar) overlying the palatopharyngeal muscle (see Figs. 14-7 and 14-11).^{3,10}

The rounded epiglottic tip rises above the level of the valleculae (see Fig. 14-1B and 14-5).^{10,11} The aryepiglottic folds connect the epiglottis with the mucosa overlying the muscular processes of the arytenoid cartilages (see Fig. 14-5). Occasionally, round bulges are seen in the lower aryepiglottic folds, reflecting the small cuneiform and corniculate cartilages embedded in these folds.

Figure 14-1 Basic structures of the normal pharynx. A. Double-contrast radiograph in the frontal view shows the contours of the superior surface of the tongue (*black arrow*), tonsillar fossa (right tonsillar fossa [*white arrow*]), valleculae (left vallecula [*v*]), and lateral wall (*open arrow*) of the piriform sinus (right piriform sinus [*p*]). The median glossoepiglottic fold (*arrowhead*) divides the space behind the tongue base into the two valleculae. The surface of the base of the tongue (*T*), seen en face, has a reticular appearance because of the underlying lingual tonsil.

B. Double-contrast radiograph in the lateral view (during phonation) shows the contours of the soft palate (*s*), base of the tongue (*t*), epiglottis (*e*), valleculae (*v*), posterior pharyngeal wall (*arrow*), barium pooling in the lower piriform sinus (*p*), and collapsed region of the pharyngoesophageal segment (*arrowheads*). Note the relative height of the soft palate with the C1 vertebral body and the thickness of the space behind the barium-coated pharyngeal mucosa, composed of pharyngeal musculature, fascial planes and prevertebral muscles, and anterior longitudinal ligament. (**B** from Rubesin SE, Jones B, Donner MW: *Contrast pharyngography: The importance of phonation*. *AJR* 148:269–272, 1987.)

Figure 14-2 Laryngeal cartilages. Plain radiograph with patient in a lateral position shows the hyoid bone (H), tip of the epiglottis (E), calcified thyroid cartilage (T), calcified superior cornu of the thyroid cartilage (arrows), and calcified cricoid cartilage (C). The soft palate (S) and base of tongue (BT) are identified. The lower hypopharynx is devoid of air. A small amount of air is seen in the laryngeal ventricle. Note the normal width of the soft tissue posterior to the pharyngeal air column.

The shape of the hypopharynx is created primarily by its relationship to the posteriorly protruding larynx (see Figs. 14-3 and 14-6B). Protrusion of the larynx into the pharynx creates two grooves in the anterior lateral hypopharynx—the piriform sinuses (recesses), pear-shaped structures that open posteriorly into the hypopharynx (see Fig. 14-6). Each piriform sinus is bounded medially by the aryepiglottic fold and mucosa overlying the muscular process of the arytenoid cartilage and laterally by the hyoid bone, thyrohyoid membrane, and thyroid cartilage.^{1,3}

The lower end of the hypopharynx is collapsed, except during passage of a bolus. The posterior portion of the larynx (including the arytenoid cartilages, arytenoid muscles, and cricoid cartilage) protrudes deeply into the lower hypopharynx (see Fig. 14-3). The upper esophageal sphincter (formed predominantly by the cricopharyngeal muscle) is tonically contracted at rest, closing the pharyngoesophageal segment (see Fig. 14-1).¹² As a result, the lower hypopharynx is markedly constricted in an anteroposterior direction and is often not appreciated on a frontal radiograph. The arcuate lower border of the hypopharynx seen on the frontal view reflects only the protrusion of the larynx into the hypopharynx (see Fig. 14-3).³

The squamous mucosa of the lateral and posterior pharyngeal walls is closely apposed to the longitudinally striated inner

longitudinal muscle layer and its aponeurosis. Only a thin tunica propria separates the epithelium from the muscle or elastic tissue of the aponeurosis. On double-contrast views, longitudinally oriented lines may therefore be seen in the lateral and posterior pharyngeal walls, reflecting apposition of epithelium to muscle (Fig. 14-8).³

Transversely oriented lines are seen on the anterior hypopharyngeal wall, where redundant squamous mucosa and submucosa overlie the muscular processes of the arytenoid cartilages and cricoid cartilage. Transverse lines and tissue bulging from the anterior wall of the pharyngoesophageal segment had previously been described as a postcricoid venous plexus.¹³ However, these radiographic findings are mainly caused by redundant mucosa and submucosa on the anterior hypopharyngeal wall (Fig. 14-9).³ Demonstration of the redundant postcricoid mucosa on a pharyngogram identifies the location of the cricopharyngeal muscle.

DIVISIONS

The pharynx is arbitrarily divided into three parts—the nasopharynx (epipharynx), oropharynx (mesopharynx), and laryngopharynx (hypopharynx).¹⁴ The nasopharynx is primarily a respiratory tract structure continuous anteriorly with the nasal cavity. The superior and posterior walls of the nasopharynx abut the basisphenoid and basilar part of the occipital bone. The nasopharynx is separated inferiorly from the oropharynx by the soft palate (see Figs. 14-4 and 14-7). The velopharyngeal portal is the opening between the nasopharynx and oropharynx.¹⁵

The oropharynx and hypopharynx are the divisions of the pharynx that participate in swallowing. The oral cavity opens into the oropharynx at the palatoglossal isthmus at the level of the anterior tonsillar pillars (palatoglossal folds; see 14-7A). The oropharynx lies posterior to the oral cavity, extending cranio-caudally from the soft palate to its arbitrary division from the hypopharynx at the level of the hyoid bone. The three divisions of the pharynx are arbitrary because the soft palate and hyoid bone change position with phonation, swallowing, and respiration. Therefore, a better dividing line between the oropharynx and hypopharynx is the pharyngoepiglottic fold (see Fig. 14-6), a mucosal fold overlying the stylopharyngeal muscle.^{1,16} The base of the tongue (see Fig. 14-1B) forms the lower anterior wall of the oropharynx.

The hypopharynx lies behind and lateral to the larynx, extending from the level of the pharyngoepiglottic fold to the lower border of the cricopharyngeal muscle at the level of the inferior margin of the cricoid cartilage. The hypopharynx communicates with the larynx at the laryngeal aditus, formed by the epiglottis, aryepiglottic folds, and mucosa overlying the muscular process of the paired arytenoid cartilages (see Fig. 14-5B). The hypopharynx communicates with the cervical esophagus at the pharyngoesophageal segment, whose walls are surrounded by the posterior lamina of the cricoid cartilage and cricopharyngeal muscle (see Fig. 14-9).

MUSCLES

Pharyngeal function depends on coordinated, sequential contraction of the extrinsic muscles of the pharynx, which arise from the skull base, neck, tongue, mandible, and hyoid bone, and the intrinsic skeletal muscles of the pharynx and larynx

Figure 14-3 Relationship of larynx to pharynx. **A.** In a patient with laryngeal penetration, barium coats the false vocal cords (right false vocal cord, F), the true vocal cords (right true vocal cord, T), and the laryngeal ventricle (right laryngeal ventricle, *black arrow*). As the larynx protrudes into the midhypopharynx, arcuate lines (*white arrows*) are formed. **B.** The relationship of the barium-coated laryngeal vestibule (*small white arrows*) to the laryngeal ventricle (*small black arrows*) is shown. Note the angle of the laryngeal ventricle atop the true vocal cords and the tilt of the true vocal cords; the posterior portion of the cords is cranial to the anterior commissure. The anterior walls of the right piriform sinus (*large white arrows*) and left piriform sinus (*large black arrows*) are seen as anteriorly convex lines. The mucosa (m) overlying the muscular process of the arytenoid cartilages lies below the aryepiglottic fold (*open arrow*). The lower hypopharynx (*arrowhead*) is closed at rest. E, epiglottis. (**B** from Rubesin SE, Glick SN: *The tailored double-contrast pharyngogram*. *Crit Rev Diagn Imaging* 28:133–179, 1988.)

Figure 14-4 Salpingopharyngeal fold. Lateral view of the nasopharynx during phonation after intranasal instillation of 1 mL of barium shows the salpingopharyngeal folds (*long black arrows*). The paired salpingopharyngeal folds overlie the salpingopharyngeal muscles. The eustachian tube orifices (one orifice identified by *short black arrow*) are manifested as barium-coated, C-shaped lines. The posterior wall of the nasopharynx is slightly irregular because of the underlying adenoidal lymphoid tissue (A). The soft palate (sp) and one palatopharyngeal fold (*white arrow*) are also demonstrated.

Figure 14-5 Folds of the valleculae. Spot radiograph with the patient in a frontal position. The folds of the epiglottis and valleculae are accentuated by edema caused by chronic radiation changes. The median glossoepiglottic fold (*black arrowhead*) divides the retroglottic space into the two valleculae (right vallecula [V]). The pharyngoepiglottic folds (*large white arrow* identifies the left pharyngoepiglottic fold) overlie the paired stylopharyngeal muscles and form part of the posterior wall of the valleculae. Also shown are the epiglottic tip (E) and left aryepiglottic fold (*black arrow*). Barium coats the laryngeal surface of the epiglottis as a result of laryngeal penetration. The interarytenoid notch (*white arrowhead*) lies between swollen mucosa overlying the muscular processes of the arytenoid cartilages.

Figure 14-6 Pharyngoepiglottic folds. **A.** Spot image obtained in the lateral projection shows the paired pharyngoepiglottic folds (*thick arrows*) coursing as oblique lines across the lateral wall of the pharynx. The pharyngoepiglottic fold overlies the stylopharyngeal muscle, which extends from the styloid process to the posterior wall of the valleculae (*v*). The uvular tip (*u*) is seen. The anterior walls of the piriform sinuses (*thin arrows*) are well visualized. The mucosa overlying the muscular processes of the arytenoid cartilages (*open arrow*) is demonstrated. **B.** Posterior view of pharynx opened from behind. On the viewer's left, the mucosa has been left intact. The epiglottis rises above the level of the valleculae, hidden in this posterior view. The uvula (*u*), palatopharyngeal fold (*p*), piriform sinus (*left dot*), and laryngeal surface of the epiglottis (*uppermost dot*) are seen en face. The pharyngoepiglottic fold (*white arrowhead*) separates the oropharynx from the hypopharynx. Bulges in the aryepiglottic fold overlie the cuneiform and corniculate cartilages (*short black arrows*). The circumvallate papillae (*short white arrow*) form a V-shaped protuberance along the base of the tongue. On the viewer's right, the mucosa has been removed. The palatopharyngeal muscle (*P*) forms the palatopharyngeal fold. This muscle has been retracted laterally. The stylopharyngeal muscle (*long white arrow*) underlies the pharyngoepiglottic fold. The thyrohyoid membrane (*long black arrow*) and internal branch of the superior laryngeal nerve (*black arrowheads*) are identified. The transverse arytenoid muscle (*single dot on viewer's right*), posterior cricoarytenoid muscle (*two adjacent dots*), and suspensory ligament of the esophagus (*s*) are identified. (**B** from Rubesin S, Jesserun J, Robertson D, et al: *Lines of the pharynx*. Presented at the 71st Scientific Assembly and Annual Meeting, Radiological Society of North America, Chicago, 1985.)

(Fig. 14-10; Table 14-1).¹⁷ The pharynx and larynx are suspended as a unit from the skull base, tongue, mandible, and hyoid bone. The suspensory muscles of the hyoid bone (the suprahyoid muscles) include the following (with their cranial nerve innervations in parentheses): from the tongue, mandible, or both, the anterior belly of the digastric muscle (V3), geniohyoid muscle (XII, via C1-2), hyoglossal muscle (XII), and mylohyoid muscle (V3); and from the skull base, the posterior belly of the digastric muscle (VII) and stylohyoid muscle (VII).^{14-16,18} The major function of the suprahyoid muscle group related to swallowing is to elevate and fix the hyoid bone, a motion that contributes to elevating and widening the pharynx, tilting the epiglottis, and opening the pharyngoesophageal segment during passage of a bolus.¹⁶

The soft palate is formed by an interweaving of muscles from the skull base (tensor veli palatini and levator veli palatini), tongue (palatoglossus muscle), and pharynx (palatopharyngeal muscle) (Fig. 14-11; see Fig. 14-7B).^{1,16,19} The musculus uvulae is the only intrinsic muscle of the soft palate.

The tendon of the tensor veli palatini (V) forms the fibrous skeleton of the anterior portion of the soft palate.¹⁶ This muscle

depresses the anterior soft palate during swallowing. The levator veli palatini (X) suspends the midportion of the soft palate (see Figs. 14-7A and 14-11). During swallowing, the levator veli palatini pulls the mid-soft palate superiorly and posteriorly.¹⁹ The palatopharyngeal muscle (X) depresses the posterior lateral part of the soft palate, elevates the pharynx, and constricts the faucial isthmus. The palatoglossus muscle (X) pulls the soft palate and tongue toward each other. The musculus uvulae (X) shortens, thickens, and elevates the uvula.

The thyrohyoid muscle (XII, via C1-2) courses from the hyoid bone to the thyroid cartilage (see Fig. 14-10). Its major function is approximation of the hyoid bone and thyroid cartilage, an action that is partly responsible for closing the laryngeal vestibule.^{16,20} The infrahyoid depressors include the sternohyoid (C1-3), sternothyroid (C1-3), and omohyoid (C1-3) muscles.¹⁶

Epiglottic tilt is accomplished via contraction of the suprahyoid muscles, thyrohyoid muscle, and intrinsic epiglottic musculature.^{10,14,21} Contraction of the suprahyoid group pulls the hyoid bone superiorly and anteriorly up underneath the mandible. Hyoid motion pulls on the hyoepiglottic ligament that courses from the inferior anterior hyoid bone to the petiole

Figure 14-7 Tonsillar fossa. **A.** Lateral drawing demonstrates the tonsillar fossa during soft palate (S) elevation by phonation. The palatine tonsil (T) is surrounded by the palatoglossal fold (anterior tonsillar pillar; *short arrow*) and palatopharyngeal fold (posterior tonsillar pillar; *long arrow*). The salpingopharyngeal fold is also shown (*arrowhead*). **B.** Sagittal view of the nasopharynx and oropharynx after removal of the overlying mucosal layer demonstrates the muscles of the soft palate and tonsillar fossa. The palatoglossus muscle (PG) pulls the midtongue and mid-soft palate together and forms the palatoglossal fold. The palatopharyngeal muscle (P) forms the palatopharyngeal fold and constricts the lateral posterior pharyngeal space. The levator veli palatini (L) pulls the midportion of the soft palate (SP) superiorly and posteriorly. The relationship between the tensor veli palatini (T) and pterygoid hamulus (H) is shown. The salpingopharyngeal muscle (S) arises from the eustachian tube cartilage and forms the salpingopharyngeal fold. Also shown is the superior constrictor muscle (C). The anterior arch of the first cervical vertebra (C1) is identified. (**A** from Rubesin SE, Rabischong P, Bilaniuk LT, et al: Contrast examination of the soft palate with cross-sectional correlation. *RadioGraphics* 8:641–665, 1988.)

Figure 14-8 Lines of the pharynx. The longitudinally striated mucosa (*white arrow*) reflects close apposition of the squamous mucosa to the underlying longitudinal muscle layer of the pharynx. Arcuate lines of the anterior hypopharyngeal wall are identified (*black arrows*).

Figure 14-9. The postcricoid "defect." **A.** During swallowing, redundant mucosa along the anterior wall of the pharyngoesophageal segment just posterior to the cricoid cartilage may create an undulating or plaque-like contour (arrows). To rule out a subtle stricture, web, or infiltrating lesion, the radiologist must be certain that this mucosal nodularity changes size and shape and flattens during swallowing. **B.** Vertically oriented, low-power photomicrograph just posterior to the cricoid cartilage (C). The squamous epithelium has an undulating contour (arrows). The tunica propria is thick, with abundant fat and several minor salivary glands (H&E stain; $\times 10$).

(lower tip) of the epiglottis.¹⁶ Hyoid motion thus pulls the lower epiglottis anteriorly and superiorly, tilting the epiglottis toward a horizontal position, as if the epiglottis were on a fulcrum. Contraction of the paired aryepiglottic and oblique arytenoid muscles pulls the epiglottic tip inferiorly. Contraction of the thyroepiglottic muscles pulls the sides of the epiglottis and aryepiglottic folds laterally.¹⁶

Closure of the laryngeal aditus is not accomplished by epiglottic inversion alone. Thyrohyoid muscle contraction pulls the hyoid and thyroid cartilage together. Closure of the vocal cords and thyroarytenoid muscles helps close the laryngeal vestibule.²⁰ Contraction of the transverse arytenoid muscle and aryepiglottic-oblique arytenoids pulls together and elevates the mucosa overlying the muscular processes of the arytenoid cartilages.¹⁶

The muscular tube of the pharynx is surrounded by the buccopharyngeal fascia.¹⁴ The buccopharyngeal fascia is separated from the prevertebral muscles and fascia by the retropharyngeal space. The retropharyngeal space is an important site for the spread of malignant and inflammatory processes.

The muscular tube of the pharynx is formed by two layers, the inner longitudinal layer and outer circular (constrictor) layer. The constrictor muscle layer (X) forms a ring that is incomplete anteriorly. During swallowing, the constrictor muscles contract sequentially to help propel the bolus into the esophagus.¹² Contraction of the superior constrictor muscles also apposes the lateral pharyngeal wall with the soft palate, closing the lateral portion of the velopharyngeal portal.^{22,23} On a lateral view of the pharynx, the location of each paired constrictor muscle can be approximated by visible structures. The

superior constrictor extends from the level of the soft palate toward the mid and lower base of tongue. The lower portion of the middle constrictor angles slightly superiorly from the level of the hyoid bone; the upper portion of the middle constrictor is about one-and-a-half vertebral bodies superior to the level of the hyoid bone. The upper border of the thyropharyngeal muscle is just above the continuation of a line of the hyoid bone posteriorly; the lowermost fibers extend to the level of redundant mucosa behind the cricoid cartilage. The redundant mucosa posterior to posterior lamina of the cricoid cartilage identifies the location of the unpaired cricopharyngeal muscle.

The inner longitudinal muscle layer (see [Figs. 14-5 through 14-7](#)) includes the stylopharyngeal muscle (IX), salpingopharyngeal muscle (X), and palatopharyngeal muscle (X).^{1,16} During swallowing, contraction of the inner longitudinal muscles helps pull the pharynx up and over the descending bolus of food.¹⁸ The palatopharyngeal muscle also constricts the posterior portion of the pharynx, channeling the bolus into the hypopharynx and helping prevent nasal regurgitation. Transfer of the bolus through the pharynx results from the pressure of the bolus itself (gravity), closure of the palatoglossal isthmus, velopharyngeal portal and laryngeal aditus, tongue base retraction, elevation of the pharynx up over bolus, and contraction of the constrictor muscles.²⁴

The pharyngoesophageal segment is tonically contracted at rest.¹² Opening of the pharyngoesophageal segment (see [Fig. 14-9](#)) is caused by gravity and muscular contractions superior to it. Signals via the recurrent laryngeal nerve cause the cricopharyngeal muscle to relax. Elevation of the pharynx and larynx by the suprahyoid musculature, intrinsic pharyngeal elevators,

Figure 14-10 Lateral view of the muscles of the pharynx. The superficial muscles, nerves, arteries, and veins have been removed. The suspensory and constrictor muscles of the normal pharynx are demonstrated. The hyoid bone is suspended anteriorly by the geniohyoid muscle (g), mylohyoid muscle (m, cut in cross section), hyoglossus muscle (h), and anterior belly of the digastric muscle (resected; not shown). The tendon connecting the anterior and posterior belly of the digastric muscle is shown (arrow). The hyoid bone is suspended posteriorly by the stylohyoid ligament, stylohyoid muscle, and posterior belly of the digastric muscle (d) (resected; not shown). The thyrohyoid muscle and ligament suspend the thyroid cartilage from the hyoid bone. The overlying depressors of the hyoid bone, the omohyoid and sternohyoid muscles, have been resected. The paired constrictor muscles of the pharynx (superior, middle, and inferior) have a C shape when viewed from above and are incomplete anteriorly. The superior constrictor muscle originates at the pterygoid plate and hamulus, at the pterygomandibular raphe with the buccinator muscle, and in the longitudinal muscles of the tongue; it joins its partner posteriorly along the median raphe of the pharynx. The middle constrictor muscle originates on the greater and lesser horns of the hyoid bone and along the lower stylohyoid ligament; it joins its partner posteriorly at the median raphe of the pharynx. The thyropharyngeal muscle (upper portion of the inferior constrictor muscle) originates from the oblique line of the thyroid cartilage; it joins its partner in the posterior median raphe. The lower portion of the inferior constrictor muscle, the cricopharyngeal muscle, arises from the lateral surface of the cricoid cartilage, encircles the pharynx, and inserts on the opposite side of the cricoid cartilage. The cricopharyngeal muscle is a C-shaped muscle without a partner and has no posterior midline raphe. (From Rubesin S, Jessorun J, Robertson D, et al: *Lines of the pharynx*. Presented at the 71st Scientific Assembly and Annual Meeting, Radiological Society of North America, Chicago, 1985.)

and thyrohyoid muscle pull the anterior wall of the pharyngo-esophageal segment (the postcricoid mucosa) superiorly and anteriorly. Pressure (weight) of the bolus, tongue base retraction, and constrictor muscle contraction help push the pharyngo-esophageal segment open.¹²

Principles of Technique

PREPARATION OF PATIENTS

High-density barium adheres to dry pharyngeal mucosa.²⁵ Despite continuous salivary secretion, the pharynx should therefore be made as dry as possible during the examination.²⁶ As a result, patients are instructed not to eat or drink after midnight on the day of the examination.⁹ In the morning, regular oral medications may be taken with small amounts of water, but insulin-dependent diabetics should not take their insulin on the morning of examination. Oral antacid medications impair barium coating and should also be avoided. If

possible, the patient should refrain from activities that stimulate salivary secretion, such as sucking throat lozenges, smoking, or chewing gum. In some inpatients, in whom the swallowing study focuses on the pharyngeal function, we allow patients to rinse their mouths with water if their mouths are dry.

COMPONENTS OF ROUTINE EXAMINATION

Contrast examination of the pharynx may be dangerous in patients with suspected airway obstruction, especially in those with acute epiglottitis.^{27,28} Lateral radiographs of the neck should therefore be obtained if airway obstruction is suspected. Lateral radiographs are also obtained for suspected foreign bodies (Fig. 14-12), fistulas, abscesses, perforations, or palpable neck masses.

Routine examination of the pharynx and esophagus includes the following: (1) videofluoroscopy or DVD recording of the oral, pharyngeal, and esophageal phases of swallowing; (2) double-contrast spot images of the pharynx, esophagus, and

TABLE 14-1 Tongue and Pharyngeal Motor Function

Figure 14-11 Muscles of the soft palate. The muscles forming the soft palate are viewed from behind, looking toward the tongue (To), nasal cavity, and sphenoid bone (S). The levator veli palatini (L) joins its partner (I; partly resected in drawing) from the opposite side to form a sling, which supports the mid-soft palate. The tensor veli palatini (T) forms a tendon that hooks around the pterygoid hamulus (H) to join its partner from the other side, forming the fibrous skeleton of the anterior soft palate. The musculus uvulae (mU), palatopharyngeal muscle (P), and eustachian tube cartilage (ETC) are also shown. (From Rubesin SE, Rabischong P, Bilaniuk LT, et al: Contrast examination of the soft palate with cross-sectional correlation. *RadioGraphics* 8:641–665, 1988.)

important. Both static and dynamic images are routinely obtained for the following reasons: (1) structural disorders often alter pharyngeal motility; (2) structural features of motility disorders are often well demonstrated on static images; and (3) structural lesions and motility disorders may coexist.

The oral and pharyngeal phases of swallowing should initially be evaluated if symptoms suggest an oral or pharyngeal disorder. If the clinical history and symptoms suggest thoracic esophageal disease, however, I only give one swallow of high-density barium in the frontal and lateral positions and then proceed to evaluate the esophagus. The radiologist should remember that the subjective sensation of dysphagia often cannot be localized accurately, and esophageal lesions may cause referred dysphagia to the neck or suprasternal region.³⁶ Furthermore, patients may have an esophageal disorder that secondarily affects pharyngeal function or a disease that involves both the pharynx and esophagus. Finally, some patients have more than one abnormality in the pharynx or esophagus, or in both.

gastric cardia; and (3) single-contrast and mucosal relief views of the esophagus (Table 14-2).²⁹⁻³⁴ The examination is tailored to the patient's clinical history, symptoms, and initial fluoroscopic findings. The pharyngoesophagogram is an interactive study; if a motility disorder is the major radiographic finding, dynamic techniques (e.g., videofluoroscopy, DVD recording) are emphasized.³⁵ If a structural abnormality is the major radiographic finding, double-contrast spot images become more

Figure 14-12 Scout radiograph prior to barium swallow. A lateral radiograph was obtained in a patient who swallowed a needle while sewing. The needle (arrow) lies adjacent to the posterior pharyngeal wall, with its sharp tip superiorly. The bulbous end of the needle is trapped just above the closed pharyngoesophageal segment.

Figure 14-13 Radiograph of the pharynx with the patient in a right lateral position, facing the examiner. The lateral view is the best view to demonstrate the vertical surface of the tongue (T), epiglottic tip (arrowhead) and aryepiglottic folds, anterior walls of the piriform sinuses (long arrows), and posterior pharyngeal wall (short arrows). Opening of the pharyngoesophageal segment is shown only during swallowing. This static radiograph shows that swallowing is abnormal because barium fills the laryngeal ventricle and coats the proximal trachea; it does not demonstrate why barium entered the larynx.

TABLE
14-2

Routine Pharyngoesophagogram for Respiratory or Pharyngeal Symptoms

View	Technique	Organ
Erect, left lateral	Videofluoroscopy, double contrast in phonation	Pharynx
Erect, frontal	Videofluoroscopy, double contrast	Pharynx
Obliques	Video, rapid sequence images if PE segment not visualized on lateral view	Pharynx
EFFERVESCENT AGENT AND WATER*		
Erect, LPO	Double contrast	Esophagus
Prone, RAO	Videofluoroscopy, single contrast	Esophagus
Right lateral	Double contrast	Gastric cardia

*If no laryngeal penetration or esophageal obstruction.

LPO, left posterior oblique with respect to table top;

PE, pharyngoesophageal; RAO, right anterior oblique with respect to table top.

DOUBLE-CONTRAST INTERPRETATION

The principles of double-contrast interpretation for studying the pharynx are the same as those for studying structures elsewhere in the gastrointestinal (GI) tract.²⁵ The double-contrast examination requires adequate mucosal coating, a sufficient number of projections, and varying degrees of luminal distention.

Mucosal Coating

Adequate mucosal coating depends primarily on two factors, dry pharyngeal mucosa and properly prepared high-density

barium (250% w/v). If the barium is too thin, the barium is of insufficient radiodensity to outline the pharyngeal mucosa. If the barium is too thick, mucosal coating may be patchy or obscure mucosal detail. Barium that is too viscous may be unable to wash and scrub the mucosa, resulting in artifactual strands of mucus. Several swallows of high-density barium may be needed in each projection to achieve uniform coating.

Projections

The lateral view best demonstrates the tonsillar fossa en face and the contours of the soft palate, base of the tongue, posterior pharyngeal wall, epiglottis, aryepiglottic folds, anterior hypopharyngeal wall, and region of the cricopharyngeal muscle in profile (Fig. 14-13; see Figs. 14-1B and 14-3B).²⁵ The lateral view is also crucial for evaluating penetration of barium into the laryngeal vestibule (Fig. 14-14). In contrast, the frontal view shows the surface of the tongue base en face and the contours of the median and lateral glossoepiglottic folds, tonsillar fossa, valleculae, and hypopharynx in profile (see Figs. 14-1A and 14-3A). Oblique views are valuable in some patients for demonstrating the obliquely oriented aryepiglottic folds, anterior walls of the piriform sinuses, and region of the pharyngoesophageal segment.^{27,32,37} Spot images obtained in frontal and lateral projections are adequate for most examinations. If a portion of the

pharynx is not well seen in frontal and lateral projections, however, the patient is turned and oblique views are obtained.

Distention

Adequate distention is important for the demonstration of mucosal surface and contour. The pharynx cannot be distended by the use of effervescent agents or tube insufflation, as in other regions of the GI tract. Instead, pharyngeal distention is achieved with phonation (the long vowel sounds “eee” or “ooo”) or some form of modified Valsalva maneuver (blowing against pursed or closed lips or whistling).^{38,39}

Phonation with “eee” expands the pharynx, resulting in better visualization of the soft palate, tonsillar fossa, base of the tongue, valleculae, epiglottic tip, aryepiglottic folds, and mucosa overlying the muscular processes of the arytenoid cartilages on the lateral view (see Fig. 14-1B).³⁹ The distal 2 cm of hypopharynx, however, remain collapsed during phonation because the pharyngoesophageal sphincter remains contracted and the larynx impresses on this region. In contrast, the distal 2 cm of the hypopharynx, pharyngoesophageal segment, and proximal cervical esophagus is optimally distended during swallowing and therefore best visualized during the dynamic phase of the examination (see Fig. 14-9).

Pharyngeal distention on the frontal view is best obtained with a modified Valsalva procedure (Fig. 14-15).^{3,25} The patient is asked to whistle or blow air out of the mouth (as if blowing out a candle) or to blow out against pursed lips. To optimize visualization of pharyngeal structures, the patient is positioned so that the mandible and hard palate are superimposed over the occiput. Flexion or extension of the neck, or protrusion or retraction of the tongue, may improve visualization of various anatomic structures such as the uvula, epiglottic tip, and lateral walls of the hypopharynx.

Figure 14-14 Laryngeal penetration. In an image obtained during swallowing, barium can be seen entering the laryngeal vestibule (white arrow). Note apposition of the hyoid bone (h) to the calcified edge of the thyroid cartilage (black arrow). (From Laufer I, Levine MS [eds]: *Double-Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 14-15 Modified Valsalva maneuver. **A.** During quiet inspiration, the right true cord (T) and false vocal cords are open. The pharynx is mildly distended. Note arcuate lines in the collapsed midhypopharynx (arrow). **B.** During a modified Valsalva, marked distention of the oral cavity and pharynx occurs. Note ballooning of the tonsillar fossae (left tonsillar fossae [TF]). Lateral pharyngeal pouches (left pouch, short thick arrow) protrude from the region of the thyrohyoid membrane. The lateral hypopharynx protrudes posterolaterally (long thin arrow) from the confines of the ala of the thyroid cartilage (short thin arrow). The lower hypopharynx, which was not apparent during inspiration, is now visible (open arrow). Protrusion of the lower hypopharynx is a sign of muscular weakness. (From Rubesin SE, Glick SN: *The tailored double-contrast pharyngogram*. *Crit Rev Diagn Imaging* 28:133–179, 1988.)

MOTILITY EXAMINATION

DVD recording and videofluoroscopy are the best methods for studying pharyngeal motility.^{29,30,40} Spot radiographs or rapid-sequence digital images are not adequate for detecting functional abnormalities. The dynamic portion of the pharyngoesophagogram focuses on patient posture and self-feeding, bolus holding anteriorly at the lips and posteriorly at the palatoglossal isthmus, tongue motion, hyoid, laryngeal, and pharyngeal elevation, soft palate elevation, formation of Passavant's cushion, pharyngeal constrictor motion, epiglottic tilt, laryngeal penetration, and cricopharyngeal muscle activity.^{31,32,40-45} An analysis of motility disorders is presented in Chapter 15.

POSITION OF THE PATIENT

The patient is first examined in the upright lateral position, which is the best position for visualizing entry of barium into the laryngeal vestibule during swallowing (penetration) or normal breathing (aspiration). If unable to stand, the patient is strapped and seated in a swallowing chair or on the footboard of the fluoroscope in a lateral position. If unable to sit, the patient is placed on the fluoroscopic table in as lateral a position as possible. Dentures are left in place because denture removal may alter swallowing dynamics. If a portable or fixed C-arm fluoroscope is available, patients may be studied while they are confined to a wheelchair or lying on a stretcher.⁴² Although the lateral view is the predominant position of the patient, the frontal view should be performed, even in debilitated patients. The frontal position demonstrates asymmetry of pharyngeal contraction and of epiglottic tilt (Fig. 14-16). Spot radiographs are performed in the frontal position, even in patients with motor disorders, because they may provide clues to the cause of a motor disorder (Fig. 14-17).³⁵

CHOICE OF CONTRAST AGENTS

In general, the pharynx manipulates a cohesive bolus more readily than a liquid bolus.^{26,43-45} Less laryngeal penetration is seen with thicker than thinner substances. Therefore, the pharyngeal phase of swallowing is usually safer with barium pudding than with thick barium and safer with thick barium than with thin barium. The caveat to "thick is safer" is that thin liquids are cleared from the pharynx better than thick liquids. Therefore, if the major abnormality is poor pharyngeal contraction leading to stasis in the piriform sinus (and epiglottic tilt is normal), a thin liquid is safer.

I usually begin an examination with thick, high-density barium because this barium best demonstrates morphologic characteristics of the pharynx. High-density barium is more visible during a review of dynamic images than thin barium. If a motility disorder is seen during fluoroscopy, swallows of thin barium are videotaped or digitally recorded in the lateral and frontal projections after double-contrast imaging of the pharynx and esophagus. Epiglottic motility is better assessed with thin barium because thick barium often obscures the epiglottic tip. Thin barium is also valuable because some patients show laryngeal penetration only with thin barium, not with thick barium or barium pudding.

If the examination is only concerned with the pharynx, I then often proceed to barium pudding or a thicker liquid

Figure 14-16 Asymmetric pharyngeal contraction demonstrated on frontal view during swallowing. Inbowing of the uppermost left lateral hypopharyngeal wall (*large arrow*) is the result of a normally contacting left thyropharyngeal muscle. The uppermost right lateral hypopharyngeal wall balloons outwardly at the level of the thyrohyoid membrane (*small arrow*), indicating lack of upper thyropharyngeal contraction.

(so-called nectar or honey) to stress the oral phase of swallowing or improve the pharyngeal phase. If the pharyngeal phase appears normal, I often stress the pharynx next with thin barium.

In general, the pharynx can manipulate small nonphysiologic boluses (2-5 mL) more safely than larger physiologic boluses (8-10 mL).^{46,47} I routinely ask outpatients to "take a normal-sized swallow of barium." If there are clinical signs of abnormal pharyngeal function, the patient should therefore be given small boluses first and then larger boluses. If I want to control the bolus size, measured amounts of barium are given with a teaspoon or small plastic measuring cup. Swallowing through a straw is relatively dangerous in a patient with abnormal oral bolus control and should be avoided until the patient is determined to be swallow-safe or to test if the patient is able to drink through a straw.

For the patient who is massively aspirating barium, the clinical status of the patient determines the number of barium swallows deemed safe for the examination. If there is aspiration of barium to or below the carina, the examination should generally be discontinued. Even with massive aspiration, views of one swallow in the lateral projection and one swallow in the frontal projection are usually obtained. A suction apparatus should be available for prompt removal of barium that enters the distal trachea.

Figure 14-17 Abnormal epiglottic tilt caused by squamous cell carcinoma involving right aryepiglottic fold and the mucosa overlying the muscular process of the right arytenoid cartilage. **A.** During swallowing, tilt of the epiglottis (E) is diminished on the right (arrow). **B.** Frontal spot radiograph shows a small mass (arrow) and thickening of the aryepiglottic fold (a) and nodular mucosa (open arrow). A small squamous cell carcinoma was found to involve the aryepiglottic fold and mucosa overlying the muscular process of the right arytenoid cartilage. (From Rubesin SE: *Pharyngeal dysfunction*. In Gore R [ed]: *Syllabus for Categorical Course on Gastrointestinal Radiology*. Reston, VA, American College of Radiology, 1991, pp 1–9.)

THERAPEUTIC EXAMINATION

A therapeutic examination of the pharynx may be performed to use modifications of swallowing that prevent or diminish laryngeal penetration and educate patients about their swallowing function.⁴⁷⁻⁴⁹ This examination is usually performed in conjunction with a swallowing therapist from the department of rehabilitation medicine or speech pathology. During the therapeutic examination, various types of boluses, head positions, and breathing techniques are used to determine which foods can be safely swallowed. The swallowing team selects a technique based on a specific abnormality seen at fluoroscopy. Most strategies to improve swallowing are temporary measures while a treatable cause of the swallowing problem is discovered or the patient recovers from a cerebrovascular accident, surgery, or radiation therapy.²⁶

Compensatory Techniques

Compensatory techniques control bolus flow but do not improve swallowing physiology. These techniques include the following: (1) changes in posture; (2) increased sensory input; and (3) alterations in food volume or consistency.⁴⁸ Eliminating food consistencies that are difficult to swallow is a short-term strategy used while a patient recovers from a swallowing disorder. Continuation of swallowing in a limited fashion may help improve muscular function and give the patient some pleasure, although not necessarily maintaining adequate hydration or nutrition. The therapist tests the patient's ability to manage barium boluses of progressively larger size and of varying viscosity. If a patient has reduced tongue motion, strength, or coordination, a thin liquid is easier to swallow. If premature

spillage of the bolus from the oral cavity to the oropharynx is observed, a thick liquid or cohesive bolus (e.g., a barium pudding) may improve the timing between the oral and pharyngeal phases. A cohesive bolus may also decrease laryngeal penetration if there is poor timing between the oral and pharyngeal phases, abnormal epiglottic tilt, or abnormal glottic closure. Conversely, a thin liquid improves pharyngeal clearance if there is stasis in the piriform sinuses, thereby diminishing overflow aspiration. Although the use of thin liquids diminishes stasis, this practice results in decreased bolus control or laryngeal penetration in patients with abnormal epiglottic tilt or abnormal laryngeal closure. Thin liquids may also improve swallowing function in patients with isolated pharyngoesophageal segment dysfunction.

Postural techniques alter oral and pharyngeal relationships and redirect bolus flow. Commonly used head positions include chin-up, chin-down, and head rotation. When there is poor transfer of the bolus from the oral cavity to the oropharynx, the chin-up position causes gravity to help the bolus fall into the oropharynx. This position requires a relatively normal pharyngeal phase of swallowing to prevent laryngeal penetration.

The chin-down (chin tuck) position is used for patients with premature spill, abnormal tongue push, laryngeal penetration resulting from abnormal epiglottic tilt, or poor opening of the pharyngoesophageal segment. If the bolus prematurely spills from the oral cavity, tucking the chin widens the valleculae, providing a space for the prematurely spilled bolus to pool rather than enter the laryngeal vestibule. The chin tuck position also improves tongue push because the tongue is positioned more posteriorly. The chin tuck position also narrows the laryngeal aditus by elevating the larynx and pharynx and tilting the

epiglottis posteriorly, diminishing laryngeal vestibule penetration caused by abnormal epiglottic tilt. Finally, the chin tuck position pulls the anterior wall of the pharyngoesophageal segment anteriorly, helping improve clearance through a pharyngoesophageal segment that opens abnormally.

Rotating the head toward one side narrows the pharynx on that side and redirects the bolus toward the opposite swallowing channel. Head rotation is used for patients with unilateral pharyngeal paresis or asymmetric epiglottic tilt to guide the bolus away from the weak side. The head is turned toward the side of weakness. Head rotation may be combined with the chin tuck maneuver.

Therapeutic Techniques

Therapeutic techniques improve motion or strength of a structure or coordination of the timing of oral and pharyngeal events.^{47,49} These include range of motion or muscle-strengthening exercises, tactile stimulation, and swallowing maneuvers.

Swallowing maneuvers include the supraglottic swallow, supersupraglottic swallow, Mendelsohn maneuver, and effortful swallow. Such maneuvers require a patient to have enough cognitive and physical ability to follow the instructions for performing these examinations.

Both a supraglottic and supersupraglottic swallow may be tried in patients who have laryngeal penetration because of abnormal timing between the oral and pharyngeal phases of swallowing or abnormal closure of the laryngeal vestibule. In a supraglottic swallow, the patient takes a bolus into the mouth, takes a breath through the nose, consciously holds the breath, swallows, and then exhales or coughs. This sequence closes the true vocal cords before and during the swallow. Exhaling or coughing after the swallow helps expel any part of the bolus that has entered the laryngeal vestibule. A supersupraglottic swallow is similar to a supraglottic swallow but uses a consciously "hard" breath-hold, which closes the true vocal cords and tilts the arytenoids forward to help close the laryngeal aditus.

such as a web or laryngeal penetration may be visible on only one or two frames at 30 frames/s.

2. The entire swallowing chain must be examined. Such extensive examination is necessary because the level of symptoms is not a reliable indicator of the site of the abnormality,¹ several lesions could be causing dysphagia, and esophageal disease may result in pharyngeal disease.²

NEUROPHYSIOLOGIC CONTROL OF SWALLOWING

Swallowing involves the close cooperation of many muscles, six cranial nerves (trigeminal, facial, glossopharyngeal, vagus, spinal branch of accessory, and hypoglossal) and the first, second, and third cervical nerves (through the ansa cervicalis). Afferent sensory information is integrated in the swallowing center in the brain stem, and efferent signals originate in the motor ganglia of the cranial nerves; movements are then effected peripherally.³⁻⁸

The vagus nerve (cranial nerve [CN] X) supplies motor efferent fibers to all the intrinsic pharyngeal muscles (constrictors, palatopharyngeus, and salpingopharyngeus), except the stylopharyngeus, which is supplied by the glossopharyngeal nerve (CN IX). The vagus nerve also supplies motor efferent fibers to all the palatal muscles, except the tensor veli palatini, which is supplied by the trigeminal nerve (CN V). The trigeminal nerve also supplies the anterior digastricus and mylohyoides. The facial nerve (CN VII) supplies the posterior digastricus and stylohyoides. Although the vagus nerve carries the efferent fibers that innervate the striated pharyngeal musculature, most of these fibers probably emerge from the brain stem in the bulbar part of the accessory nerve (CN XI).

Pharyngeal branches of the glossopharyngeal and vagus nerves and rami of the sympathetic trunk and superior cervical ganglion form a plexus in the connective tissue outside the constrictor muscles (the pharyngeal plexus). In this plexus, autonomic (parasympathetic and sympathetic) and afferent and efferent branchial fibers intermingle and branch into the muscles and the mucosal lining. Damage to this plexus can produce dysphagia.^{9,10}

Pharyngeal sensation, including sensation of the tonsil and postsulcal part of the tongue, appears to be mediated by the glossopharyngeal nerve. This nerve also supplies motor innervation to the stylopharyngeus and parasympathetic secretomotor fibers to the parotid gland.

FUNCTIONAL COMPONENTS OF SWALLOWING

Oropharyngeal Phase

Tongue and Palate. Swallowing begins with the lips engulfing the bolus (Figs. 15-1 and 15-2). The bolus is then manipulated by the tongue and teeth until it is judged "swallowable." Two positions of the bolus preparatory to swallowing have been

Analysis of the Functional Aspects of Swallowing

In reviewing the pharyngeal swallow, the slow motion, reverse, and stop-frame capabilities of videofluorography are essential. With these capabilities, the movement of individual structures can be analyzed, first in isolation and then in combination with other structures, including the tongue, palate, epiglottis, hyoid bone, larynx, and cricopharyngeus. Esophageal peristalsis should also be evaluated, but discussion of this subject is beyond the scope of this chapter.

Familiarity with the anatomy, radiographic anatomy, and physiology of the pharynx and related structures is a necessity for abnormalities to be appreciated. Any lack of movement or abnormalities indicating compensation or decompensation must be noted.

Two important principles must be considered when reviewing pharyngeal studies:

1. Dynamic imaging is vital. Pharyngeal contraction occurs much faster than esophageal contraction (12-25 cm/s vs. 1-4 cm/s), which is why dynamic imaging is essential when examining the pharynx. In addition, an abnormality

Figure 15-1 Line drawing of the normal swallow (lateral view). **A.** The bolus is held in the oral cavity by apposition of the soft palate and back of the tongue. **B.** As the bolus is presented to the oropharynx, the soft palate (short arrow) elevates to appose Passavant's cushion (long arrow) to prevent nasopharyngeal regurgitation. **C.** As the bolus passes through the pharynx, the beginning of the posterior pharyngeal stripping wave (yellow arrow) can be seen. The epiglottis (black arrow) is tilted to cover the laryngeal aditus, which is completely closed. **D.** As the bolus descends farther, the back of the tongue, soft palate, and pharyngeal stripping wave (arrow) continue to seal the nasopharyngeal inlet, the epiglottis remains tilted, and the larynx remains closed. The cricopharyngeus has opened completely to allow unimpeded bolus passage. **E.** As the bolus descends past the cricopharyngeal level, the tongue base begins to move forward, and the soft palate begins to elevate. **F.** As the bolus passes into the thoracic esophagus, the tongue base moves forward, the epiglottis flips up, and the larynx returns to its resting, open position. (From Donner MW, Bosma JF, Robertson DL: *Anatomy and physiology of the pharynx*. *Gastrointest Radiol* 10:196–212, 1985.)

identified: the tipper type (in which the bolus is held in the midline groove of the tongue) and the dipper type (in which the bolus is held anteriorly underneath the tongue in the floor of the mouth).¹¹

The back of the tongue blade and soft palate form a seal that prevents premature leakage into the pharynx before swallowing (see Figs. 15-1A and 15-2A). Weakness, atrophy, or resection of the tongue or soft palate can lead to aspiration before swallowing because of leakage of the bolus into the open, unprotected larynx. Viewed in the frontal position, unilateral leakage indicates decompensation on one side only.

As the bolus is propelled into the oropharynx by an upward backward movement of the tongue, the soft palate elevates to a right angle to appose the posterior pharyngeal wall, with Passavant's cushion moving anteriorly to complete the seal of the palatopharyngeal isthmus. Passavant's cushion results from focal contraction of the upper fibers of the superior pharyngeal constrictor muscle (Fig. 15-3; see also Figs. 15-1B, 15-2B, 15-10A, 15-11A, and 15-11B). Tongue thrust (involving first the blade and then the base of the tongue), combined with pharyngeal constriction and intrabolus pressure, result in bolus propulsion.

Pharynx. The constrictor stripping wave can be observed at the tail of the bolus in the lateral position as a progressive forward movement of the posterior pharyngeal wall (see Figs. 15-1C to F and 15-2C to E). In the frontal position, the wave can be appreciated as the lateral walls of the pharynx converge to the midline, completely obliterating the pharyngeal cavity behind the bolus. Unilateral weakness results in asymmetry on the frontal view, with one side moving to the midline and the other remaining still or bulging during the swallow. Sometimes, the contracting normal side can displace the bolus across to the atonic side, so the bolus passes down the paralyzed side. The contracting normal side may be misinterpreted as a mass, whereas the abnormality is actually on the noncontracting bulging side. Contraction of the constrictor muscles may be affected by intrinsic disease of the pharyngeal muscles (e.g., polymyositis), neuromuscular disorders (e.g., amyotrophic lateral sclerosis, cerebrovascular accident [CVA]), or local factors (e.g., scarring, radiation, cervical spine disease). Large osteophytes in the cervical spine may hinder or prevent epiglottic tilt.¹² Diseases that restrict laryngeal elevation (e.g., radiation, head and neck surgery) may compound the problem.

Figure 15-2 The normal swallow. **A** to **F.** A series of stop-frame prints from a cinepharyngoesophagogram shows the normal swallow as it appears on the dynamic imaging study in the lateral position. The epiglottis (*arrowheads*) and stripping wave (*arrow*) are identified. Note that the superior and posterior surfaces of the soft palate have been coated by intranasal injection of barium. **F.** The epiglottis is beginning to re-elevate but has not yet returned to its resting position. *b*, Bolus; *p*, Passavant's cushion; *u*, soft palate.

Laryngeal Dynamics and Hyoid Elevation

Respiration is suspended during swallowing and resumes after swallowing. As the bolus enters the oropharynx, the larynx begins to elevate, the hyoid bone moves upward and forward, and the true vocal folds, false vocal folds, and laryngeal vestibule close inferiorly to superiorly, with the vestibule closing last. Laryngeal elevation begins simultaneously with elevation of the

hyoid bone but continues for a short time after the hyoid bone has reached its peak elevation. Laryngeal movement can be appreciated by observing the hyoid bone rising to appose the angle of the mandible. There is an excellent review of laryngeal dynamics by Curtis.¹³ A direct correlation exists between hyoid bone excursion and bolus volume, with larger volumes producing more elevation.¹⁴ Hyoid bone elevation may occur in one step (20%) or in two steps (80%), whereas descent occurs in

Figure 15-3 Multiple stop-frame prints from four different patients show multiple decompensations.

A. Somewhat magnified view of the lateral oropharynx and nasopharynx demonstrates incomplete elevation of the soft palate (u) and marked nasopharyngeal regurgitation (arrows). **B.** There is unilateral leakage over the back of the tongue (arrows) into the left vallecula (V) and then into the piriform sinus (P). **C.** Lateral view shows marked laryngeal penetration into the widely open larynx (arrowheads) and incomplete elevation of the hyoid bone (arrows); normally, the hyoid elevates almost to the angle of the mandible (M). **D.** There is marked retention in the valleculae (V) and piriform sinuses (PS) after swallowing and overflow aspiration (arrows) into the larynx and trachea (T). (B from Jones B, Donner MW: *Interpreting the study*. In Jones B, Donner MW [eds]: *Normal and Abnormal Swallowing: Imaging in Diagnosis and Therapy*. New York, Springer-Verlag, 1991, p 60.)

one step, simultaneously with return of the epiglottis to the upright position.¹⁵

A recent review of the literature of hyoid and laryngeal kinematics¹⁶ has revealed a large variability in the values reported for superior hyoid displacement, varying from 5.8¹⁷ to 25.0 mm.¹⁸ Anterior displacement similarly ranged from 7.6¹⁹ to 18 mm.²⁰ Another recent study²¹ has correlated hyoid displacement with cervical spine height (measuring from the anteroinferior border of C4 to the anteroinferior border of C2) and compared findings in men and women. When adjusted for height, the upward movements of the hyoid and larynx were similar in magnitude in men and women.

Epiglottic Tilt

Epiglottic tilt deflects food and liquid into the lateral food channels away from the larynx; when completely inverted, the epiglottis covers the laryngeal aperture. In many people, this movement occurs in two steps; the first movement (to a horizontal position) is probably a passive one caused by elevation

of the hyoid bone and the second movement (to complete inversion) is probably caused by contraction of the thyroepiglotticus.²² In a minority of people, the epiglottis fails to invert, tilting only to the horizontal or oblique position. In the frontal view, the completely inverted epiglottis produces a seagull-shaped filling defect. Flow of the bolus into the lateral food channels may also produce a flow defect, or pseudomass.

Cricopharyngeal Opening

Pharyngeal constriction must be coordinated with cricopharyngeal relaxation and opening. The cricopharyngeus must relax and open completely to allow unimpeded bolus passage.²³⁻³⁸ Opening of the lumen at the pharyngoesophageal junction results from several actions: (1) cricopharyngeal relaxation; (2) superior and anterior movement of the larynx, resulting in traction on the anterior wall of the lumen; (3) pharyngeal constriction, producing thrust; and (4) intrabolus pressure, producing thrust. Thus, cricopharyngeal prominence is often observed in patients with pharyngeal paresis or a frozen larynx.

Figure 15-4 Cricopharyngeal prominence. Frontal (A) and lateral (B) radiographs show prominence of the cricopharyngeus (arrows). Note the jet effect below the narrowing (arrowheads), simulating a stenotic lesion, especially on the lateral view. The lumen of the cervical esophagus is actually dilated because the patient had achalasia. (From Jones B, Donner MW, Rubesin SE, et al: *Pharyngeal findings in 21 patients with achalasia of the esophagus*. *Dysphagia* 2:87–92, 1987.)

In such cases, the pharyngeal milieu, rather than the muscle itself, is abnormal.

Radiographically, one normally observes luminal opening, not cricopharyngeal relaxation; a radiographic report therefore should not comment on cricopharyngeal relaxation but only on cricopharyngeal opening. *Cricopharyngeal achalasia* is a manometric term referring to complete failure of cricopharyngeal relaxation, an unusual entity. Other common conditions associated with cricopharyngeal prominence include Zenker's diverticulum, advanced age, gastroesophageal reflux, and other esophageal motility disorders (e.g., diffuse esophageal spasm, achalasia; Fig. 15-4).² The resulting luminal compromise may be minimal or marked. In severe cases, there may be a horizontal bar. The luminal narrowing can be treated by endoscopic bougienage.

Pharyngeal Residue

The normal swallow should clear most of the bolus from the mouth and pharynx. (An exception is high-density barium designed to coat the gastrointestinal [GI] tract). A study by Dejaeger and colleagues in 1997³⁹ studied mechanisms involved in postdeglutition residue in older adults and found that retention in the valleculae and piriform sinuses was related to markedly reduced pharyngeal shortening, a low tongue-driving force, and diminished amplitude of pharyngeal contraction. Retention in the valleculae only is related to a low tongue-driving force and in the piriform sinuses only is related to reduced pharyngeal shortening.

Prevention of Aspiration

Many mechanisms protect the larynx from aspiration (see Figs. 15-3 and 15-11). Laryngeal elevation and closure of the vocal folds, arytenoid cartilages, and laryngeal vestibule all contribute, as does epiglottic tilt.⁴⁰ Thus, a frozen larynx can result in aspiration.

If aspiration is observed, all factors that prevent aspiration should be analyzed and the following questions asked:

- Does the epiglottis tilt, and does the larynx (hyoid bone) elevate adequately?
- Do the vocal cords and laryngeal vestibule close?

It should also be noted when the aspiration occurs in relation to swallowing. Laryngeal penetration or aspiration through the vocal folds may occur during swallowing, before swallowing (premature leakage from the mouth), or after swallowing (overflow aspiration of a retained bolus in the pharynx, or regurgitated of refluxed material). The timing and causes of aspiration have potential therapeutic implications.

Another important observation is whether the aspirated material precipitates a cough; this needs to be conveyed to the referring physician in the radiologic report. Some patients with chronic aspiration are silent aspirators, presumably because of loss of laryngeal sensation. Bedside evaluation of these patients for aspiration is notoriously unreliable. In fact, the so-called bedside evaluation underestimates the possibility of aspiration in many patients.^{41–44}

The important role that the mouth can play in aspiration was underestimated until two important studies highlighted the role of oral decompensation alone in aspiration.^{45,46} Feinberg and Ekberg studied a group of 50 patients with known aspiration; they found that aspiration was the result of oral decompensation alone in 23 patients, a combination of oral and pharyngeal decompensation in 17 patients, and pharyngeal decompensation alone in 10 patients.⁴⁵ The same authors studied oral decompensation in 75 patients who survived a near-fatal choking episode.⁴⁶ Abnormalities were found on videography in 58 of these 75 patients. Oral stage dysfunction was the predominant finding in 32 patients, with pharyngeal abnormalities in 19 and cricopharyngeal abnormalities in 28.

Reduced vertical excursion of the hyoid or larynx may contribute to incomplete airway closure and the risk of aspiration.⁴⁷ Reduced anterior displacement may result in reduced upper

esophageal sphincter (UES) and cricopharyngeal (CP) opening, contributing to piriform sinus residue.⁴⁸

Adaptation, Compensation, and Decompensation

The pharynx is an extremely flexible organ that must adapt to its various functions, including respiration, speech, and swallowing. In addition, the pharynx adapts to different stimuli, such as the size and consistency of the bolus and temperature of ingested liquids and food; the pharynx compensates when one of its parts is defective. The process of adjustment of normal swallowing to different stimuli is called *adaptation*.⁴⁹ The pharynx must adjust to the bolus, which may vary in volume, temperature, consistency, viscosity, and elasticity. The effect of different boluses can be seen with videofluoroscopy by watching the difference between a swallow of thin liquid barium and a swallow of the same volume of barium paste.⁵⁰

The effect of a carbonated bolus on the physiology of the swallow has been investigated.⁵¹ Carbonated liquids reduced penetration, aspiration, and pharyngeal retention, and pharyngeal transit time was shorter.

When signs of compensation are visible on dynamic studies, swallowing is already impaired.⁴⁹ Some types of compensation for impaired swallowing may be conscious and voluntary. For example, a patient may change the types of foods eaten, perhaps omitting solid food and substituting puréed food, or may even restrict the diet to liquids only. Certain postures such as flexing the neck (chin tuck) or turning the head may help a patient swallow more effectively, reducing laryngeal penetration or aspiration and clearing any retained bolus.

Swallowing can be considered to have five distinct stages, each of which has a characteristic pattern of compensation and decompensation.⁴⁹ The five stages include the following:

1. Control of the junction of the mouth and pharynx (palatoglossal seal; Fig. 15-5)
2. Closure of the palatopharyngeal isthmus (Fig. 15-6)

Figure 15-5 Control of the junction of the mouth and pharynx. **A.** Leakage from the back of the mouth is prevented in the normal patient when the soft palate abuts the posterior portion of the tongue. **B.** Deficiency of the tongue caused by atrophy, weakness, incoordination, or postsurgical defect may be compensated by downward displacement of the palate (arrow), with the palate “kinking” to appose the tongue. **D.** Conversely, palatal deficiency is compensated by upward displacement of the tongue (arrow). Note that the bolus is held further forward in the mouth under these circumstances. **C, E.** Decompensation, in which there is premature leakage of oral contents into the pharynx (arrow), with the potential for overflow aspiration. (From Buchholz DW, Bosma JF, Donner MW: *Adaptation, compensation, and decompensation of the pharyngeal swallow*. *Gastrointest Radiol* 10:235–240, 1985.)

Figure 15-6 Closure of palatopharyngeal isthmus during swallowing. **A.** Normal closure, in which the soft palate has elevated to a right angle to abut Passavant’s cushion. **B.** Deficiency of the pharyngeal palate may be compensated by increasing convergence of the pharyngeal constrictor muscles (arrow), resulting in a very prominent Passavant’s cushion. **C.** Decompensation results in nasopharyngeal regurgitation through the palatopharyngeal isthmus (arrow). (From Buchholz DW, Bosma JF, Donner MW: *Adaptation, compensation, and decompensation of the pharyngeal swallow*. *Gastrointest Radiol* 10:235–240, 1985.)

Figure 15-7 Compression of the bolus. **A.** Normal compression. **B.** Deficiency of the constrictor muscles may be compensated by increased upward and posterior displacement of the tongue and larynx (arrow). **D.** Deficiency of the tongue in bolus compression may be followed by more anterior displacement of the constrictor wall (arrow), resulting in a very prominent pharyngeal stripping wave. **C, E.** Decompensation caused by inadequate bolus compression results in bolus retention in the valleculae and piriform sinuses after swallowing, with the potential for overflow aspiration. (From Buchholz DW, Bosma JF, Donner MW: Adaptation, compensation, and decompensation of the pharyngeal swallow. *Gastrointest Radiol* 10:235–240, 1985.)

Figure 15-8 Closure of the larynx. **A.** The normal condition, in which the larynx is elevated and closed, and the epiglottis (arrow) is completely tilted down to cover the entrance to the laryngeal aditus. **B.** With deficiency of epiglottic tilting or glottic closure, there may be increased upward and anterior displacement of the larynx (arrow). Under these circumstances, the arytenoid masses may be enlarged as a sign of compensation (not illustrated). **C.** Failure of compensation results in penetration of bolus (arrow) into the laryngeal vestibule, and even through the incompletely closed cords, with aspiration. (From Buchholz DW, Bosma JF, Donner MW: Adaptation, compensation, and decompensation of the pharyngeal swallow. *Gastrointest Radiol* 10:235–240, 1985.)

3. Compression of the bolus (Fig. 15-7)
4. Closure of the larynx (Fig. 15-8)
5. Opening of the pharyngoesophageal segment (Fig. 15-9)

During the first stage, for example, downward placement of the soft palate may compensate for deficiencies of the tongue (resulting from atrophy, weakness, or surgical resection). Conversely, upward displacement of the tongue may compensate for weakness of the soft palate (see Figs. 15-5 to 15-9 for compensation occurring during other stages of swallowing). Another compensatory phenomenon is the development of a deeper pharyngeal stripping wave, which may be observed in the presence of a partially obstructing lesion in the cervical esophagus, such as a web or cricopharyngeal bar.

Any radiographic findings of compensation must be communicated to the referring physician so the patient can be informed that swallowing is impaired. The patient can then be instructed to take additional care when eating or drinking quickly—for example, in a restaurant or in other social situations.

Functional Aspects of Zenker's Diverticulum

Zenker's diverticulum is a pulsion diverticulum located at the level of the pharyngoesophageal junction; the most common site is between the oblique and horizontal fibers of the cricopharyngeal muscle through a triangular area known as Killian's dehiscence (Fig. 15-10). It is a posterior diverticulum that may fill during or after swallowing and, if large, may flop to one side or the other. Once swallowing is completed, the diverticulum may empty back into the pharynx, filling the piriform sinuses. This often precipitates a second swallow but also places the patient at risk for overflow aspiration.

The pathogenesis of Zenker's diverticulum remains unclear, but incoordination between pharyngeal contraction and cricopharyngeal opening may be a contributing factor.⁵²⁻⁵⁵ Manometric and cineradiographic studies have demonstrated premature sphincter closure in some patients with Zenker's

Figure 15-9 Opening of the pharyngoesophageal segment. **A.** Normal opening of pharyngoesophageal segment. **B.** Deficiency of upward laryngeal displacement, which contributes to opening of the pharyngoesophageal segment, results in flexion of the neck and/or forward thrusting of the jaw during swallowing. **C.** Failure of compensation results in poor pharyngoesophageal segment opening, with retention of the bolus in the piriform sinuses and the risk of overflow aspiration. (From Buchholz DW, Bosma JF, Donner MW: Adaptation, compensation, and decompensation of the pharyngeal swallow. *Gastrointest Radiol* 10:235–240, 1985.)

Figure 15-10. Zenker's diverticulum. **A.** Lateral view shows a small diverticulum (Z) above a very prominent cricopharyngeus (large white arrow) causing luminal narrowing of at least 50%, with a jet of barium (arrowheads) below it. The cervical esophageal lumen is actually abutting the spine (small white arrows). Also note nasopharyngeal regurgitation (black arrow) and marked degenerative changes in the cervical spine. **B.** After swallowing, Zenker's diverticulum (Z) remains filled. **C.** Frontal view in another patient shows emptying of the diverticulum (Z) back into the pharynx (arrows) after swallowing, placing this patient at risk for overflow aspiration. Also note the buccal pouch on the left side (arrowhead). (From Jones B, Donner MW [eds]: *Normal and Abnormal Swallowing: Imaging in Diagnosis and Therapy*. New York, Springer-Verlag, 1991.)

diverticulum. Other studies performed in patients with fully developed diverticula, however, have shown that the timing of pharyngeal contraction and cricopharyngeal relaxation may be normal.

Cook and associates demonstrated decreased compliance of the UES in a group of patients with Zenker's diverticulum, in whom inadequate sphincter opening resulted in increased intrabolus pressure.^{56–58} Shaw and co-workers subsequently demonstrated that with cricopharyngeal myotomy and pouch ablation, the intrabolus pressure fell and full UES opening was restored.^{59,60} They also observed structural abnormalities in muscle strips of the cricopharyngeus in 14 patients with Zenker's diverticulum.⁶¹ They found type 1

fiber predominance and greater fiber size variability. The muscles also demonstrated fibroadipose tissue replacement and fiber degeneration. These studies suggest that decreased UES compliance may have a major role in the development of Zenker's diverticulum.

Gastroesophageal reflux may also contribute to the development of Zenker's diverticulum.^{62–65} In an analysis of 67 patients with Zenker's diverticulum, 63 were found to have esophageal pathology such as gastroesophageal reflux, spasm, or hiatal hernia (T. Karaho, unpublished data, 1998).

Radiologically, Zenker's diverticulum is usually associated with prominence of the cricopharyngeus or a cricopharyngeal bar. Esophageal disease may produce prominence of the

cricopharyngeus, perhaps with decreased compliance, which in turn may raise intrapharyngeal and intrabolus pressure, necessitating more forceful contraction, with eventual bulging through a congenitally weak area. Further studies are necessary (including those addressing the early developmental stages of Zenker's diverticulum) before the pathophysiology can be fully understood.

Interrelationships

ESOPHAGEAL DISTENTION AND THE CRICOPHARYNGEUS

Intraluminal foreign bodies lodged in the hypopharynx or upper esophagus may produce cricopharyngeal spasm.⁶⁶ In cats, it has been shown that stimulation of afferent receptors in the hypopharynx or upper cervical esophagus evokes reflex contraction and spasm in the cricopharyngeal muscle, with an increase in intraluminal pressure in the sphincter segment. Similarly, esophageal distention by liquids or an intraluminal balloon in humans results in elevated pressure in the sphincter segment.⁶⁷⁻⁶⁹

GASTROESOPHAGEAL REFLUX AND THE CRICOPHARYNGEUS

There are variable reports in the manometric literature as to whether acid bathing the esophagus produces a rise in pressure in the UES. In the 1970s, studies in human volunteers using perfused catheters reported elevated pressures in the sphincter segment after infusion of the esophagus with saline or acid.^{70,71} The closer the infusion was to the UES, the greater the increase in pressure. In the late 1980s, a study using a modified sleeve sensor compared UES pressures in normal persons and patients with esophagitis⁷²; this study reported no UES response to acid reflux or acid perfusion. Another manometric study using solid-state catheters has shown many interactions among the lower esophageal sphincter, gastroesophageal reflux, intraesophageal pressure changes, and changes in pressure in the UES.⁷³

Several reflexes have been described, primarily by Shaker and co-workers⁷⁴⁻⁷⁸:

1. UES contractile response to gastroesophageal reflux. Torrico and colleagues compared UES pressure changes in normal controls and patients with reflux esophagitis⁷³; most of the controls and patients with reflux esophagitis had a significant increase in UES pressures in response to reflux episodes.
2. UES contractile response. Mechanical stimulation of the pharynx in cats and water stimulation in humans⁷⁵ results in an increase in UES resting tone. As little as 0.1 mL of water produced this reflex.
3. Esophagoglottal closure reflex. Esophageal distention during gastroesophageal reflux could overwhelm the UES, with the potential for overflow aspiration. A reflex has been described in humans⁷⁸ and cats⁷⁶ in which esophageal distention resulted in reflex closure of the glottis.
4. Pharyngoglottal adduction reflex. An injection of minute amounts of water into the pharynx resulted in brief closure of the vocal folds. This was thought to be a protective reflex to prevent aspiration.⁷⁸

SWALLOWING-RELATED REFLEXES

Many cardiorespiratory reflexes are related to swallowing, resulting from laryngeal, pharyngeal, or esophageal stimulation. Examples include syncope, change in heart rate, apnea, and bronchoconstriction leading to asthma.⁷⁹⁻⁸³ A review of swallowing-related reflexes is referenced for further reading.⁸⁴

Functional Changes After Radiation Therapy

Radiotherapy with or without chemotherapy is a common treatment for head and neck cancers. Dysphagia is a common result of the treatment. Approximately 80% of patients being treated with radiotherapy develop mucositis.⁸⁵ Mucositis is most marked over the arytenoids, but the epiglottis and posterior pharynx are also affected. Endothelial vasculitis results in localized ischemia, which in the long term may result in fibrosis.

Several studies of the long-term effect of radiation therapy on swallowing have been reported.^{86,87} Abnormalities included paresis of constrictor muscles, bolus retention, laryngeal penetration, and aspiration, often silent. Absent epiglottic tilt was common. Incomplete cricopharyngeal opening and reduced tongue base retraction was present.

Logemann and colleagues⁸⁸ reported on swallowing disorders in the first year after radiation and chemoradiation in 48 patients. Chemoradiation resulted in fewer functional swallows than radiation alone. The authors compared pretreatment videofluoroscopic swallowing study (VFSS) results with findings at 3 months and 12 months. All 48 patients had abnormal swallows pretreatment, probably related to the presence of the tumor. The most frequent abnormalities were reduced tongue base retraction, reduced tongue strength, and a delay in pharyngeal triggering. Other findings included delayed laryngeal closure and reduced laryngeal elevation. Two other studies compared the effects of chemoradiation on voice and swallowing.^{89,90}

Postradiation xerostomia often compounds swallowing difficulties. One study compared the findings in 15 cancer patients and 20 controls.⁹¹ Patients with xerostomia took almost twice as long to chew a shortbread cookie, but the duration of swallowing was unaffected. For liquid barium and paste, timing measures were the same for controls and for patients with xerostomia. Attempts are being made to modify radiotherapy regimens (organ preservation regimens) by collimating the radiation to avoid the pharyngeal constrictors and spare the parotids, so xerostomia is not as common a problem.

Aging and Swallowing

Swallowing in older individuals is called *presbyphagia*.⁹² Presbyphagia may be considered under two separate categories: (1) the effects of the normal aging process on swallowing (primary presbyphagia); and (2) the effects on swallowing of other diseases that affect older adults, such as CVAs and Parkinson's disease (secondary presbyphagia).

Prevalence studies have shown that the incidence of dysphagia is 12% to 13% in teaching hospitals and as high as 59% in nursing homes.⁹³ Up to 74% of nursing home residents

were reported to have feeding disorders.^{94,95} Although there is little loss of functional motor neurons before 60 years of age, a striking and progressive depletion of functioning motor neurons occurs after this age, with subsequent deterioration of connective tissue, loss of elasticity, and atrophy of fat.⁹⁶ In the oropharynx, the suspensory ligaments of all structures become lax, resulting in premature leakage, low positioning of the hyoid, squaring of the valleculae, and expansion of the pharyngeal cavity.⁹⁷⁻¹⁰¹ Loss of pliability may also result in incomplete inversion of the epiglottis and incomplete closure of the larynx.¹⁰²

In one study, defective closure of the laryngeal vestibule with laryngeal penetration was found in 70 of 101 patients over 80 years of age.¹⁰³ Thus, laryngeal penetration in older adults may be a normal finding. The laryngeal epithelium appears to become less sensitive to aspirated material with increasing age, which may explain why silent aspiration can be a problem.¹⁰⁴ In addition, airway protection may be further compromised by medications for depression, anxiety, or Parkinson's disease. One study found no significant change in the velocity of peristalsis with increasing age.¹⁰⁵ However, the oral and pharyngeal phases may become uncoupled, resulting in delayed initiation of pharyngeal contraction and early cricopharyngeal closure. With aging, there is also a decrease in how long the pharyngoesophageal segment remains open to allow bolus passage.⁹⁸

Borgstrom and Ekberg studied swallowing function in an asymptomatic group of 56 patients ranging from 72 to 93 years of age.¹⁰⁵ Normal deglutition (as defined in younger persons) was found in only 16% of patients. Oral abnormalities were found in 63%, pharyngeal abnormalities in 25%, and pharyngoesophageal segment abnormalities in 39%.

A review of dysphagia in older adults is recommended for further reading.¹⁰⁶ A discussion of changes in esophageal motility that occur with increasing age is beyond the scope of this chapter.

Neurologic Disease and the Pharynx

Neuromuscular disorders may cause dysphagia by affecting the afferent or efferent limbs of the swallowing reflex and by producing abnormalities at many levels, including the cerebral cortex, cranial nerve nuclei in the brain stem, cranial nerves themselves, pharyngeal plexus, neuromuscular junction, muscles, or sensory feedback mechanisms.¹⁰⁷⁻¹¹⁵ Dysphagia can be a minor or major symptom; occasionally, it may be the predominant or only complaint. For example, acute onset of dysphagia may signal focal brain stem stroke, and chronic dysphagia may be the presenting symptom of an unrecognized neuromuscular disease such as amyotrophic lateral sclerosis. At the Johns Hopkins Swallowing Center, approximately 30% of patients have dysphagia in the setting of neuromuscular disease; dysphagia was the predominant or only symptom in 10% of these patients. (B. Jones, personal observation).

CEREBROVASCULAR ACCIDENT

Formerly, it was thought that a unilateral abnormality of one corticobulbar tract did not produce a major swallowing deficit because each corticobulbar tract supplies both sides of the brain stem with cortical input. Despite the supposed bilateral

representation of swallowing, however, dysphagia occurs in 20% to 40% of patients with cerebrovascular accidents,¹¹⁰⁻¹¹⁸ including those with unilateral strokes. Robbins and co-workers have challenged the theory of bilateral representation of swallowing.^{119,120} They studied patients with unilateral cortical strokes (as diagnosed by computed tomography [CT]) and compared swallowing abnormalities in the group with infarcts in the right cerebral cortex to those in the group with infarcts in the left cerebral cortex. Initiation of the pharyngeal phase of swallowing was delayed in all patients. However, patients with left cortical strokes showed impaired oral stage function, difficulty initiating coordinated motor activity, and apraxia, whereas pharyngeal pooling, penetration, and aspiration were more prominent in patients with right cortical strokes.

In 1990, Alberts and associates studied the sensitivity of magnetic resonance imaging (MRI) for CVA.¹²¹ They found that 1.5-T imaging was positive in 66 of 71 patients with CVAs. They also evaluated the occurrence of aspiration after CVA in 38 patients and correlated the incidence of aspiration with the site of the lesion.¹²² The highest frequency of aspiration was found in large vessel pontine lesions (80%). Pontine infarctions of the middle cerebral artery (MCA), posterior cerebral artery (PCA), or cerebellum (large vessel) resulted in aspiration in approximately 66% of patients. Periventricular small vessel disease resulted in aspiration in slightly less than half (48%).

Two reviews on swallowing and functional MRI are suggested to the reader.^{123,124} MRI, however, is not infallible and may be negative in patients with focal strokes.^{125,126}

Wallenberg's syndrome is a CVA involving the medulla (lateral medullary infarction) in the distribution of the posterior inferior cerebellar artery. Traditional teaching had stressed that the resulting pharyngeal paresis was unilateral, but two studies found that the deficit is actually bilateral.^{127,128} Lateral medullary infarction can also lead to aphagia.¹²⁹

AMYOTROPHIC LATERAL SCLEROSIS (LOU GEHRIG'S DISEASE)

Amyotrophic lateral sclerosis, also known as motor neuron disease or Lou Gehrig's disease, can result in bulbar palsy, pseudobulbar palsy, or a combination of both. The disease may produce a wide spectrum of abnormal findings, including muscle weakness and atrophy of the lips, tongue, palate, and pharyngeal constrictors, with various degrees of retention of secretion.¹³⁰⁻¹³⁴ Weakness of the intrinsic laryngeal muscles leads to airway penetration and aspiration. The tongue, hyoid, and larynx are weak and ptotic in the upright position. The patient will often compensate by holding the head and neck in a position of sustained extension (swan neck) to help maintain the airway and facilitate swallowing.

MULTIPLE SCLEROSIS

Corresponding to the course of the disease itself, swallowing impairment in multiple sclerosis is relapsing and remitting.¹³⁵⁻¹³⁷ The radiographic appearance depends on the location and extent of the demyelination process. Abnormalities may vary from difficulty initiating swallowing to episodes of choking on liquids or sticking of solid particles. Sensory loss may compound the problem, and symptoms may be minimal or absent, even in the presence of severe decompensation.

NEURODEGENERATIVE DISORDERS

Parkinson's disease is associated with dysphagia in as many as 50% of patients. Delayed initiation of swallowing and oral transfer problems predominate. The findings include lingual tremor or rocking, squeezing of the bolus between the tongue and palate, piecemeal deglutition, and hesitancy to propel the bolus into the pharynx.¹³⁸⁻¹⁴¹

Huntington's disease,^{142,143} progressive supranuclear palsy,¹⁴⁴⁻¹⁴⁶ and Alzheimer's disease¹⁴⁷ may also produce dysphagia and feeding difficulties. The oropharyngeal findings simulate those of Parkinson's disease. Dementia, other cognitive problems, and uncontrolled movements may complicate feeding and rehabilitation.

Similarly, dystonia and dyskinesia may result in dysphagia or feeding difficulties because of involuntary localized muscle contractions.¹⁴⁸ In dystonia, the tonically contracted tongue, positioned in a tight mass in the back of the oral cavity, produces a characteristic appearance, the so-called fistled tongue. To swallow, the patient tilts his or her head into extreme extension and appears to decant the bolus into the pharynx by gravity.¹⁴⁸

MYASTHENIA GRAVIS AND RELATED DISORDERS

Myasthenia gravis^{149,150} and the Eaton-Lambert myasthenic-myopathic syndrome¹⁵¹ are myoneural junction disorders with diminished release or inadequate binding of acetylcholine. In addition to ocular and proximal limb weakness, there may be dysphagia or choking, characteristically appearing late in the day. Slowing of swallowing or decompensation after repetitive swallowing may suggest the diagnosis during dynamic imaging.

The Eaton-Lambert myasthenic-myopathic syndrome (carcinomatous neuropathy) is usually seen with oat cell carcinoma of the lung but has also been reported in association with carcinoma of the breast, prostate, stomach, and rectum.¹⁵¹ Diplopia, dysarthria, and dysphagia may accompany weakness of muscles of the trunk, pelvis, and shoulder girdle, the most common sites affected.

Botulism also affects transmission at the myoneuronal junction and may result in dysphagia. Interestingly, botulin toxin has been used to treat a variety of dystonias, including torticollis; dysphagia may occur as a side effect in a small number of patients because of diffusion of the toxin into the soft tissues of the neck and pharyngeal musculature.¹⁵²

FAMILIAL DYSAUTONOMIA (RILEY-DAY SYNDROME)

A characteristic finding is delayed cricopharyngeal opening with airway penetration.¹⁵³

Diseases of the Muscle

Diseases prominently affecting muscles may be caused by inflammatory disease (e.g., polymyositis, dermatomyositis, sarcoidosis)¹⁵⁴ metabolic or endocrine disease (e.g., mitochondrial myopathy or ragged red fiber disease),^{155,156} dysthyroid myopathy (e.g., hypothyroidism, hyperthyroidism), or muscular dystrophy.¹⁵⁷ Polymyositis or myopathy may

also be caused by a prolonged course of steroid therapy. Muscular dystrophies affecting the pharynx include myotonic dystrophy, Duchenne's muscular dystrophy, and oculopharyngeal dystrophy.¹⁵⁸⁻¹⁶¹ There is bilateral pharyngeal paresis with bolus retention; the cricopharyngeus may be prominent but closes with normal timing. The use of chilled barium accentuates the abnormalities in myotonic dystrophy.¹⁶¹

Infections

Viral infections of the nervous system may cause dysphagia. For example, a patient with bulbar poliomyelitis can present with pharyngeal paralysis, aspiration, and disturbance of vasomotor control when motor neurons in the medullary reticular formation, especially those in or near the nucleus ambiguus, are involved. Acute bulbar poliomyelitis is now rare in countries with mass vaccination but is still seen in areas where vaccination is not widespread.

A postpolio syndrome has been described, with symptoms of increasing weakness beginning 20 or more years after the acute attack of poliomyelitis; symptoms may include dysphagia.¹⁶²⁻¹⁶⁶ In a minority of patients, these symptoms are progressive; this has been called postpolio progressive muscle atrophy.¹⁶²⁻¹⁶⁶

Buchholz and Jones reported 13 patients with a remote history of acute poliomyelitis and dysphagia.¹⁶⁴ None of these 13 patients reported progressive dysphagia, and constrictor weakness was found in 11. Subsequently, Jones and co-workers reviewed the dynamic imaging studies of 20 patients with dysphagia and a remote history of polio.¹⁶⁵ Multiple abnormalities were present in these patients, including atrophy of prevertebral soft tissue, pharyngeal paresis or paralysis with bolus retention after swallowing, incomplete or absent epiglottic tilt, laryngeal penetration or aspiration, a cricopharyngeal bar, palatal weakness, incomplete laryngeal closure, and poor or absent laryngeal elevation (Fig. 15-11).

Sonies and Dalakas evaluated 32 postpolio patients with videofluoroscopy and ultrasound; 18 of these patients did not report dysphagia.¹⁶⁶ Despite the lack of symptoms, 17 of 18 patients had abnormalities of oropharyngeal function of varying severity.

Medications

Medications may cause localized pill-induced pharyngitis or esophagitis.¹⁶⁷ They may also induce or aggravate myasthenia gravis, dystonia, and myopathy or neuropathy.¹⁶⁸⁻¹⁸⁰ More than 30 medications in current clinical use may interfere with neuromuscular transmission, including antibiotics such as neomycin, streptomycin, and some tetracycline and immunosuppressive agents, such as adrenocorticotrophic hormone (ACTH), prednisone, and azathioprine. Sedatives, antipsychotic drugs, and antidepressants may produce extrapyramidal symptoms and signs of muscle spasm or dystonia or may unmask a latent neuromuscular disease. Ideally, such medications should be temporarily stopped for several days before a swallowing study. Tryptophan use has been associated with the development of an eosinophilia-myalgia syndrome.¹⁸¹⁻¹⁸³ Studies suggest that this association is caused by a chemical constituent related to the specific manufacturing conditions rather than to the tryptophan itself.¹⁸³

Figure 15-11 Postpolio dysphagia. **A.** Lateral view shows incomplete elevation of the soft palate (U) and minimal nasopharyngeal regurgitation (open arrow). Passavant's cushion is not evident. The bolus is past the epiglottis (solid arrows), which has remained almost completely upright, and there is incomplete elevation of the hyoid bone (h), which has not moved anteriorly. **B.** There is bulging of the pharynx, so it is overlapping the cervical spine (black arrows) with laryngeal penetration (white arrow). There is prominence of the cricopharyngeus (arrowhead) and poor distention of the cervical esophagus below the cricopharyngeus. Also note nasopharyngeal regurgitation (open black arrow). **C.** Frontal view shows asymmetric distention, with the left piriform sinus (PS) bulging much more than the right because of pharyngeal constrictor weakness. There is a small amount of barium in the laryngeal vestibule (arrow) and a moderate pseudomass effect caused by a flow defect (arrowheads). **D.** After passage of the bolus, there is marked retention in the left piriform sinus (PS), which is larger than the right, and mild retention in the right piriform sinus. There is also asymmetric retention in the vallecula on the left side (V). Barium is also seen in the laryngeal vestibule and ventricle (arrow).

Structural Abnormalities of the Pharynx

STEPHEN E. RUBESIN

CHAPTER OUTLINE

Pharyngeal Pouches and Diverticula

Lateral Pharyngeal Pouches and Diverticula

Laryngoceles

Branchial Cleft Cysts, Branchial Cleft Fistulas, and Branchial Pouch Sinuses

Zenker's Diverticulum

Lateral Cervical Esophageal Pouches and Diverticula

Pharyngeal and Cervical Esophageal Webs

Inflammatory Lesions of the Pharynx

Lymphoid Hyperplasia of the Lingual and Palatine Tonsils

Benign Tumors of the Pharynx

Malignant Tumors of the Pharynx

Signs and Symptoms

Squamous Cell Carcinoma

Lymphoma

Rare Malignant Tumors

Pharyngeal Damage from Radiation

Postoperative Pharynx

Total Laryngectomy

Pharyngolaryngectomy

Esophageal Speech

Neck Dissection

Voice-Sparing Procedures

Surgery for Tongue and Oropharyngeal Cancers

Tracheostomy

Surgery for Zenker's Diverticulum and Pharyngeal Pouches

Cricopharyngeal Myotomy

Pharyngeal Pouches and Diverticula

LATERAL PHARYNGEAL POUCHES AND DIVERTICULA

The lateral pharyngeal wall may protrude beyond the normal expected contour of the pharynx in areas unsupported by muscle layers. The upper anterolateral pharyngeal wall is poorly supported in the region of the posterior and superior portions of the thyrohyoid membrane.¹ This region is bounded superiorly by the greater cornu of the hyoid bone, anteriorly by the thyrohyoid muscle, posteriorly by the superior cornu of the thyroid cartilage and stylopharyngeal muscle, and inferiorly by the ala of the thyroid cartilage.² This unsupported part of the thyrohyoid membrane is perforated by the superior laryngeal

artery and vein and the internal laryngeal branch of the superior laryngeal nerve.¹

Patients with lateral pharyngeal pouches usually have no symptoms. Approximately 5% of people with lateral pharyngeal pouches complain of dysphagia, choking, or regurgitation of undigested food.³⁻⁵ Lateral pharyngeal pouches are extremely common, and the frequency of their occurrence increases with age.¹ The pouches are usually bilateral.

On frontal views during swallowing, pouches appear as transient, hemispheric, contrast-filled protrusions from the lateral hypopharyngeal wall, below the hyoid bone and above the calcified edge of the thyroid cartilage (Fig. 16-1). The junction of the ala of the thyroid cartilage and thyrohyoid membrane is seen on frontal views as a notch in the lateral pharyngeal wall.² On double-contrast frontal views in which a modified Valsalva maneuver is performed, the pouches are seen as hemispheric, barium-coated protrusions above the notch in the lateral pharyngeal wall.² On lateral views, the pouches are seen as oval ring shadows (occasionally with an air-contrast level) below the hyoid bone at the level of the valleculae, just behind the epiglottic plate, along the anterior hypopharyngeal wall.^{1,2} Barium that is retained in pouches during swallowing spills into the ipsilateral piriform sinus after the bolus passes. This delayed spill may result in dysphagia or a choking sensation because of overflow aspiration.^{4,5}

In contrast, lateral pharyngeal diverticula are persistent protrusions of pharyngeal mucosa, usually through the thyrohyoid membrane or, rarely, through the tonsillar fossa.^{1,2} The diverticula are lined by nonkeratinizing squamous epithelium surrounded by loose areolar connective tissue, with many vascular spaces.³ These protrusions are commonly found in those who have increased intrapharyngeal pressure (e.g., wind instrument players, glass blowers, people with severe sneezing episodes). Clinical symptoms may include dysphagia, choking, cough, hoarseness, regurgitation of undigested food, or a painless neck mass.^{1,3} Radiographically, the diverticula are persistent, barium-filled sacs of various sizes connected to a bulging lateral hypopharyngeal wall by a narrow neck (Fig. 16-2). They are usually unilateral.

LARYNGOCELES

A lateral pharyngeal diverticulum is a protrusion of nonkeratinizing squamous mucosa originating in the pharynx. A laryngocele is a protrusion of ciliated pseudostratified columnar epithelium and loose areolar connective tissue arising from saccular dilation of the appendix of the laryngeal ventricle.^{6,7} If saccular dilation of the appendix is confined by the thyroid cartilage, it is termed an *internal laryngocele*. If the dilation extends above the thyroid cartilage and through the thyrohyoid membrane, the sac is termed *external*

Figure 16-1 Lateral pharyngeal pouches. Frontal view of the pharynx obtained as the bolus is passing through the lower pharynx and pharyngoesophageal segment. Barium is retained in the right and left lateral pharyngeal pouches (arrows). The pouches protrude through the region of the thyrohyoid membrane.

laryngocele. A combination of internal and external laryngocele is termed a *mixed laryngocele*.

Patients with laryngoceles and those with lateral pharyngeal diverticula have similar symptoms and physical findings. Most patients are asymptomatic and in the fifth to sixth decade of life.⁶ Patients with external or mixed laryngoceles may have a compressible lateral neck mass. Patients with internal laryngoceles may complain of hoarseness, dysphagia, or choking. Laryngoceles are seen in patients with increased intralaryngeal pressure, such as glass blowers and wind instrument players.

Frontal radiographs in patients with an external laryngocele may show an air-filled sac above and lateral to the ala of the thyroid cartilage. Lateral radiographs may show the air-filled sac anterior to the epiglottic plate, in contrast to a lateral pharyngeal diverticulum, which lies posterior to the epiglottic plate.¹ External and internal laryngoceles do not fill with barium on pharyngograms. However, barium studies may reveal enlargement of the aryepiglottic fold with a smooth overlying mucosa.

BRANCHIAL CLEFT CYSTS, BRANCHIAL CLEFT FISTULAS, AND BRANCHIAL POUCH SINUSES

In the 4-week-old embryo, paired grooves of ectodermal origin, termed *branchial clefts*, appear on both sides of the neck region.^{6,8} Branchial ridges (arches) lie between the branchial clefts. Four outpouchings from the pharynx grow to meet the branchial clefts. The pharyngeal outpouchings are of endodermal origin and are termed *branchial pouches*. The first branchial cleft forms the external auditory meatus. The second branchial cleft forms the middle ear, eustachian tube, and floor of the tonsillar fossa. The third and fourth branchial pouches form the piriform sinuses.⁸

Figure 16-2 Lateral pharyngeal diverticula. **A.** Frontal view shows a round saclike structure (open arrow) protruding from the left lateral pharyngeal wall. This lateral pharyngeal diverticulum contains an air-contrast level. A right lateral diverticulum is faintly seen as a bilobed structure (solid arrows). V, Left vallecula. **B.** Lateral view shows that the left lateral pharyngeal diverticulum (open arrow) is behind and at the level of the vallecula (V). In this slightly tilted view, the bilobed right lateral pharyngeal diverticulum (short arrows) is faintly seen. Long arrows indicate the aryepiglottic folds. E, epiglottic tip. (A and B modified from Rubesin SE, Glick SN: *The tailored double-contrast pharyngogram*. Crit Rev Diagn Imaging 28:133–179, 1988.)

Persistence of branchial pouches or clefts results in the formation of sinus tracts or cysts. The most common branchial vestige is a cyst arising from the second branchial cleft. A second branchial cleft cyst is found at the level of the hyoid bone, deep to the sternocleidomastoid muscle.⁶ Pathologically, a unilocular cyst is lined by keratinizing, stratified, squamous epithelium and is filled with desquamated keratinaceous debris. A zone of lymphoid tissue surrounds the epithelium.⁶

Patients with second branchial cleft cysts usually present between the ages of 10 and 40 years with a painless or fluctuant mass in the upper neck along the upper third of the anterior border of the sternocleidomastoid muscle.⁹ When small, the cysts are anterior to the sternocleidomastoid muscle. When large, the cysts may extend posteriorly to the sternocleidomastoid muscle, displacing the carotid sheath.

Cross-sectional imaging of noninfected cysts may reveal a smooth, thin-walled mass with a homogeneous water core.¹⁰ If infected, the wall of the branchial cleft cyst becomes thickened and may enhance with the administration of intravenous contrast medium.¹⁰ The second branchial cleft cyst may extend between the internal and external carotid arteries at a level superior to their bifurcation. Rarely, branchial cleft cysts may communicate with the pharynx (branchial cleft fistulas), filling with barium during pharyngography.¹

Branchial pouch sinuses or fistulas are tracts that extend from the pharynx and end blindly in the soft tissues of the neck (sinus) or extend to the skin (fistulas). These tracts are lined by ciliated columnar epithelium. Branchial pouch sinuses arise from the tonsillar fossa (second pouch), upper anterolateral piriform fossa (third pouch), or lower anterolateral piriform sinus (fourth pouch; Fig. 16-3). Many of these fistulas are present at birth⁹ and communicate with the skin. Sinus tracts that end blindly are occasionally seen in adults.

ZENKER'S DIVERTICULUM

Zenker's diverticulum (posterior hypopharyngeal diverticulum) is an acquired mucosal herniation through an area of anatomic weakness in the region of the cricopharyngeal muscle (Killian's dehiscence). The inferior constrictor muscle is composed of the thyropharyngeal and cricopharyngeal muscles. The thyropharyngeal muscle arises from the lateral ala of the thyroid cartilage; it courses laterally and posteriorly to merge with its counterpart from the opposite side in a raphe in the posterior pharyngeal wall. The cricopharyngeal muscle constitutes the lower portion of the inferior constrictor muscle, arising from the lateral cricoid cartilage to encircle the lowermost hypopharynx. The cricopharyngeal muscle has no midline raphe. No overlap of fibers exists between the thyropharyngeal and cricopharyngeal muscles. Considerable variation is found in the arrangement of the muscle bundles of the thyropharyngeal and cricopharyngeal muscles. Killian's dehiscence has been variably described as arising between the thyropharyngeal and cricopharyngeal muscles or between the oblique and horizontal fibers of the cricopharyngeal muscle.^{11,12} This area of weakness occurs in one third of patients.¹³

The pathogenesis of Zenker's diverticulum is as controversial as the muscular anatomy. Some radiographic and manometric studies have suggested that spasm with elevated pressure of the upper esophageal sphincter or incoordination and abnormal relaxation of the upper esophageal sphincter (achalasia) are contributing factors. However, other manometric studies have

Figure 16-3 Fourth branchial pouch sinus. Spot radiograph of the pharynx obtained with patient in a left posterior oblique position shows a thin, 1.5-cm barium-filled track (white arrow) arising from the anterolateral wall of the lower left piriform sinus. The track has a saccular configuration at its termination (black arrow).

shown the following: (1) there is normal coordination between pharyngeal contraction and relaxation of the upper esophageal sphincter; (2) the upper esophageal sphincter relaxes completely during swallowing (i.e., there is no achalasia); and (3) the resting pressure of the upper esophageal sphincter is low (i.e., there is no spasm).^{14,15} The relationship between gastroesophageal reflux disease and Zenker's diverticulum is also controversial. Almost all patients with Zenker's diverticulum have an associated hiatal hernia,^{16,17} and many patients have radiographic evidence of gastroesophageal reflux, reflux esophagitis, or both. Whether gastroesophageal reflux predisposes patients with a large Killian dehiscence to the formation of Zenker's diverticulum is unknown.

Zenker's diverticulum is usually found in older patients who have dysphagia, regurgitation of undigested food, halitosis, choking, hoarseness, or a neck mass. Some patients with Zenker's diverticulum are asymptomatic.

During swallowing, Zenker's diverticulum appears as a posterior bulging of the lowermost hypopharyngeal wall above an anteriorly protruding pharyngoesophageal segment (cricopharyngeal muscle; Fig. 16-4). The neck of the Zenker's diverticulum can be very broad during swallowing. At rest, the barium-filled diverticulum extends below the level of the cricopharyngeal muscle posterior to the proximal cervical esophagus (Fig. 16-5). After swallowing, barium in the diverticulum is regurgitated into the hypopharynx. In some patients, this regurgitation of barium results in overflow aspiration.

Figure 16-4 Zenker's diverticulum during swallowing. The relationship between the mouth of the Zenker's diverticulum and prominent cricopharyngeus is demonstrated. **A.** The bolus approaches the closed pharyngoesophageal segment (arrow), but barium has entered the mouth (double arrow) and lumen of the Zenker's diverticulum (Z). The mouth of a Zenker's diverticulum can be very broad, often larger than 1 cm. **B.** Most of the bolus has passed through the pharynx. The pharynx and larynx have continued to rise (≈ 3 mm), and the anterior wall of the trachea has been pulled forward slightly. The pharyngoesophageal segment is now open (double arrow). Redundant mucosa is seen in the postcricoid region (arrow). Opening of the pharyngoesophageal segment depends on elevation and anterior movement of the larynx, as well as the pressure of the bolus caused by gravity, tongue base thrust, and constrictor muscle contraction.

Figure 16-5 Zenker's diverticulum. **A.** Frontal view of the pharynx shows a 3- x 4-cm barium-filled sac (Z) midline below the tips of the piriform sinuses. Barium also coats the vocal cords because of an abnormal epiglottic tilt. **B.** A lateral view obtained while the patient is drinking shows the Zenker's diverticulum as a barium-filled sac (Z) posterior to the cervical esophagus (white arrowhead). The opening of the sac is superior to the posterior wall of the pharyngoesophageal segment (double arrow). The pharyngoesophageal segment is mildly narrowed. Also note diminished epiglottic tilt (black arrowhead) and laryngeal penetration.

A true Zenker's diverticulum may be confused with barium trapped above a cricopharyngeal muscle that has closed before the pharyngeal contraction wave has passed. This barium, trapped between downwardly progressing pharyngeal contraction and the cricopharyngeal muscle, is termed a *pseudo-Zenker's diverticulum* (Fig. 16-6). Barium may also be trapped above early closure of the upper cervical esophagus. Incomplete opening and early closure of the cricopharyngeal muscle, and early closure of the upper cervical esophagus, have been associated with gastroesophageal reflux disease.¹⁸

The complications of Zenker's diverticulum include bronchitis, bronchiectasis, lung abscess, diverticulitis, ulceration, fistula formation, and carcinoma.¹⁹ Any change in the character of dysphagia or bloody discharge in a patient known to have Zenker's diverticulum should suggest a complication.²⁰ On barium studies, irregularity of the contour of Zenker's diverticulum should suggest an inflammatory or neoplastic complication. Carcinoma arises in less than 1% of patients with Zenker's diverticulum,²⁰ but it is usually fatal.

LATERAL CERVICAL ESOPHAGEAL POUCHES AND DIVERTICULA

The Killian-Jamieson space is a triangular area of weakness in the cervical esophagus just below the cricopharyngeal muscle. This space is bounded superiorly by the inferior margin of the cricopharyngeal muscle, anteriorly by the inferior margin of the cricoid cartilage, and inferomedially by the suspensory ligament of the esophagus originating from the posterior wall of the cricoid cartilage, just before the tendon forms the longitudinal muscle of the esophagus.^{21,22}

Transient or persistent protrusions of the anterolateral cervical esophagus into the Killian-Jamieson space are termed *lateral cervical esophageal pouches* or *diverticula*, respectively. They are also known as *Killian-Jamieson pouches* or *Killian-Jamieson diverticula*. Most patients with Killian-Jamieson diverticula are asymptomatic, but some may complain of dysphagia or regurgitation.

These pouches and diverticula are relatively common and may be confused radiographically with Zenker's diverticulum. Killian-Jamieson diverticula can be bilateral or unilateral. If unilateral, the diverticula are usually found on the left side of the proximal cervical esophagus.²³ Radiographically, a small (3-20 mm in diameter), round to ovoid, smooth-surfaced out-pouching is seen just below the level of the cricopharyngeal muscle (Fig. 16-7).²³ On frontal views, pouches appear as small, round, or ovoid protrusions of the lateral upper esophageal wall that are filled late during swallowing and that empty after swallowing.²² Diverticula appear on frontal views as saccular protrusions that have narrow necks (see Fig. 16-7) and do not empty as quickly after swallowing. On lateral views, the anterior wall of the sac is anterior to the cervical esophagus, below the level of the cricopharyngeal muscle.²³ In contrast, the neck of Zenker's diverticulum is on the posterior hypopharyngeal wall, and the sac extends inferiorly behind the cervical esophagus.

Pharyngeal and Cervical Esophageal Webs

Webs are thin mucosal folds usually located along the anterior wall of the lower hypopharynx and proximal cervical

Figure 16-6 Pseudo-Zenker's diverticulum. **A.** During barium drinking, no pouch is seen as the bolus passes through the pharyngoesophageal segment. **B.** A view taken just after the swallow passes shows barium trapped (arrow) above an early-closing cricopharyngeal bar. This barium passed through the pharyngoesophageal segment seconds later.

Figure 16-7 Killian-Jamieson diverticulum. **A.** Frontal view of the pharynx shows a barium-filled sac (K) to the left of the cervical esophagus. The neck of the diverticulum (long arrow) is below the level of the cricopharyngeal muscle (short arrow). **B.** Lateral view shows the diverticulum (K) protruding anterior to the course of the cervical esophagus (arrows). (From Rubesin SE: *Pharynx*. In Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

esophagus. They are usually composed of normal epithelium and lamina propria.²⁴ Some webs show inflammatory changes.

The cause and clinical significance of webs are controversial. Most patients with cervical esophageal webs are asymptomatic. The webs are seen as isolated findings in 3% to 8% of patients undergoing upper GI barium studies.²⁵⁻²⁹ In one autopsy series, 16% of patients had incidental cervical esophageal webs.²⁴

Some pharyngeal and cervical esophageal webs are associated with diseases that cause inflammation and scarring, such as epidermolysis bullosa or benign mucous membrane pemphigoid. Several older northern European series showed an association of cervical esophageal webs, iron deficiency anemia, and pharyngeal or esophageal carcinoma.^{30,31} This association was termed *Plummer-Vinson syndrome* or *Paterson-Kelly syndrome*. In the United States, no strong association of cervical esophageal webs, iron deficiency anemia, and pharyngoesophageal carcinoma has been found. Webs in the distal esophagus have been associated with gastroesophageal reflux disease.²⁵ Some cervical esophageal webs may also be associated with gastroesophageal reflux.²⁷

Some webs are present in the valleculae or lower piriform sinus. These vallecular and piriform sinus webs are composed of mucosa, lamina propria, and underlying blood vessels. These webs are thought to be normal variants in the valleculae and piriform sinuses.³²

Webs appear radiographically as 1- to 2-mm wide, shelflike filling defects along the anterior wall of the hypopharynx or cervical esophagus (Fig. 16-8). The webs protrude to various depths into the esophageal lumen. Webs may extend laterally, and a few extend circumferentially. Circumferential webs appear as ringlike shelves in the cervical esophagus. With severe luminal narrowing, dysphagia may result, especially in patients with circumferential cervical esophageal webs. Partial obstruction is suggested by a jet phenomenon^{33,34} or by dilation of the esophagus or pharynx proximal to the web (see Fig. 16-10). A dynamic examination reveals a higher percentage of webs than spot images alone. Better demonstration of webs is also achieved with the use of large boluses of barium.²⁸

Webs may be confused radiographically with redundant mucosa in the anterior wall of the pharyngoesophageal segment at the level of the cricoid cartilage. This redundant mucosa has been termed the *postcricoid defect* and was previously attributed to a venous plexus in this region.³⁵ However, the postcricoid defect is probably related to redundancy of the mucosal and submucosal tissue in this area.² Webs also should not be confused with a prominent cricopharyngeal muscle, which appears as a round, broad-based protrusion from the posterior pharyngeal wall at the level of the pharyngoesophageal segment.

Figure 16-8 Partially obstructing cervical esophageal web. Frontal (A) and lateral (B) views show a circumferential radiolucent ring (white arrows) in the proximal cervical esophagus. Partial obstruction is suggested by a jet phenomenon (black arrows), with barium spurting through the ring, and by mild dilation of the proximal cervical esophagus (c). The level of the cricopharyngeus is identified (curved arrow in A). (From Rubesin SE: *Pharynx*. In Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Inflammatory Lesions of the Pharynx

Although acute epiglottitis usually affects children between 3 and 6 years of age, it occasionally causes severe stridor and sore throat in adults.³⁶ Plain radiographic diagnosis of acute epiglottitis is important (even in adults) because manipulation of the tongue or pharynx may exacerbate edema and respiratory distress. Neck radiographs may show smooth enlargement of the epiglottis and aryepiglottic folds. Barium studies are contraindicated because they may exacerbate edema, triggering an episode of acute respiratory arrest.³⁷

Barium studies of the pharynx are usually of limited value in patients with acute sore throat caused by viral, bacterial, or fungal infection.³⁷ Such patients usually demonstrate normal findings on pharyngograms or evidence of nonspecific lymphoid hyperplasia of the palatine or lingual tonsils.

In immunosuppressed patients with acute dysphagia, barium studies are directed toward the esophagus to demonstrate the presence, site, and type of esophagitis. However, double-contrast examination of the pharynx may demonstrate the plaques of *Candida* pharyngitis or the ulcers of herpes pharyngitis, particularly in patients with AIDS (Fig. 16-9).³⁸

In patients with chronic sore throat, barium studies may help determine whether underlying gastroesophageal reflux and reflux esophagitis are present. Inflammatory disorders of the pharynx or gastroesophageal reflux can alter pharyngeal elevation, epiglottic tilt, or closure of the vocal cords and laryngeal vestibule. Inflammation-induced dysmotility may result in laryngeal penetration and stasis.

Some diseases with diffuse mucous membrane ulceration affect the pharynx. Pharyngeal inflammation and ulceration may be seen in patients with Behçet's syndrome, Stevens-Johnson syndrome, Reiter's syndrome, epidermolysis bullosa,^{39,40} or bullous pemphigoid.⁴¹ Most of these patients have recurrent aphthous stomatitis and oropharyngeal ulceration. With severe ulceration, amputation of the uvula and tip of the epiglottis may be observed radiographically.⁴¹ Scarring may cause distortion of the pharyngeal contours. Severe ulceration with subsequent scarring may also be caused by lye ingestion (Fig. 16-10).⁴²

LYMPHOID HYPERPLASIA OF THE LINGUAL AND PALATINE TONSILS

The lingual tonsil is an aggregate of 30 to 100 follicles along the pharyngeal surface of the tongue, extending from the circumvallate papillae to the root of the epiglottis.⁴³ This lymphoid tissue causes the normal surface of the base of the tongue to be divided into small nodules of varying size.

Hypertrophy of the lingual tonsil frequently occurs after puberty, as a compensatory response after tonsillectomy, or as a nonspecific response to allergies or repeated infection.⁴³ Symptoms attributed to lymphoid hyperplasia of the lingual tonsil include throat discomfort, a globus sensation, and dysphagia. There are no criteria based on size for differentiating nodularity of the base of the tongue because of normal lingual tonsils from that resulting from reactive lymphoid hyperplasia. On frontal radiographs obtained in patients with lymphoid

Figure 16-9 Lymphoid hyperplasia of the base of the tongue. Frontal view shows large, smooth-surfaced, round to ovoid nodules (arrow) symmetrically distributed over the surface of the base of the tongue.

hyperplasia, multiple smooth, round, or ovoid nodules are symmetrically distributed over the surface of the base of the tongue (Fig. 16-11). On lateral radiographs, the base of the tongue may seem to protrude posteriorly. In lymphoid hyperplasia of the palatine tonsils, masslike enlargement of the palatine tonsils is seen in the frontal and lateral views (Fig. 16-12). With severe lymphoid hyperplasia of the base of the tongue, the nodules may extend into the valleculae, along the lingual surface of the epiglottis, or even into the upper hypopharynx. Lingual tonsil lymphoid hyperplasia can be coarsely nodular, asymmetrically distributed, or masslike. However, any asymmetrically distributed coarse nodularity or mass must be viewed with suspicion. The use of endoscopy and magnetic resonance imaging (MRI) may help exclude malignancy.

Benign Tumors of the Pharynx

A wide variety of benign tumors occur in the pharynx.⁶ Non-epithelial tumors arising from the supporting tissues of the pharynx are rare.^{44,45} However, tumor-like cysts of various histologic types are not uncommonly seen in the pharynx.⁴⁶ The most common benign lesions are retention cysts of the valleculae or aryepiglottic folds.

Symptoms are related primarily to the location and polypoid or sessile nature of the lesion. Patients with benign tumors of the base of the tongue may be asymptomatic or may

complain of throat irritation or dysphagia. Aryepiglottic fold nodules or mass lesions may cause dysphonia or respiratory symptoms such as stridor. Tumors of the epiglottis and aryepiglottic folds may also result in dysphagia, coughing, or choking because of laryngeal penetration. Rarely, pedunculated lesions (e.g., papillomas, lipomas,⁴⁷ fibrovascular polyps) may be coughed up into the mouth or may cause sudden death through asphyxiation.

Tumors of various histologic types tend to occur at specific locations in the pharynx. Retention cysts and granular cell tumors are the most common benign tumors of the base of the tongue (Fig. 16-13).⁴⁸ Ectopic thyroid tissue and thyroglossal duct cysts may occur at the tongue base but are rare. The tumor-like lesions that usually involve the aryepiglottic folds are retention cysts and saccular cysts. Retention cysts of the aryepiglottic folds are lined by squamous epithelium and filled with desquamated squamous debris (Fig. 16-14). In contrast, saccular cysts of the aryepiglottic folds arise from the mucus-secreting glands of the appendix of the laryngeal ventricle and are filled with mucoid secretions. True soft tissue tumors of the aryepiglottic folds, such as lipomas, neurofibromas, hamartomas,⁴⁵ granular cell tumors, and oncocytomas, are rare.⁶ Laryngeal involvement in neurofibromatosis (von Recklinghausen's disease) is rare but usually involves the region of the arytenoid cartilage and aryepiglottic folds.⁴⁹ Benign tumors arising from the minor mucoserous salivary glands are usually seen in the oropharynx in the region of the soft palate and base of the tongue. Benign cartilaginous tumors involving the pharynx (chondromas) usually arise from the posterior lamina of the cricoid cartilage.⁵⁰

Regardless of its underlying histologic characteristics, a benign pharyngeal tumor usually appears radiographically as a smooth, round, sharply circumscribed mass en face and as a hemispheric line with abrupt angulation in profile (see Figs. 16-16 and 16-17).^{37,48} Only rarely is a pedunculated polypoid lesion (e.g., papilloma, fibrovascular polyp) seen. The benign nature of these lesions should be confirmed by endoscopic examination. However, submucosal masses are sometimes missed at endoscopy.

Malignant Tumors of the Pharynx

Radiologists should be as familiar with pharyngeal carcinoma as they are with esophageal carcinoma. Squamous cell carcinomas of the head and neck (e.g., tongue, pharynx, larynx) constitute 5% of all cancers in the United States, whereas esophageal carcinomas constitute only 1% of all cancers. The radiologist may be the first physician to suggest a diagnosis of pharyngeal carcinoma (Fig. 16-15). Some tumors may be detected during barium studies performed for other reasons. Patients with pharyngeal symptoms or a palpable neck mass may undergo pharyngoesophagography as the initial diagnostic examination. In patients with known pharyngeal cancer, a contrast examination is of value to assist in planning proper work-up and therapy. A barium examination can also be used to rule out a second primary lesion in the esophagus. Furthermore, the examination can detect coexisting structural lesions (e.g., prominent cricopharyngeal muscle, Zenker's diverticulum, web, stricture) that may be difficult to circumvent safely at endoscopy. Barium studies reveal the size, extent, and inferior limit of pharyngeal tumors and the degree of functional impairment. The barium examination can also show areas behind

Figure 16-10 Lymphoid hyperplasia of the palatine tonsils. Frontal (A) and lateral (B) views of the pharynx show bilateral, symmetric enlargement of the palatine tonsils (arrows).

bulky tumors that are difficult to visualize by endoscopic examination.

Barium studies allow detection of more than 95% of structural lesions below the pharyngoesophageal fold.⁵¹ These studies are especially valuable in areas of the pharynx that are difficult to evaluate by endoscopy (e.g., lower base of the tongue, valleculae, lower hypopharynx, pharyngoesophageal segment).

SIGNS AND SYMPTOMS

The symptoms of pharyngeal carcinoma are nonspecific and usually of short duration (<4 months). They include sore throat, dysphagia, and odynophagia. Choking or coughing may be caused by laryngeal penetration during swallowing or aspiration of barium trapped in ulcerated tumors. Hoarseness occurs primarily in patients with laryngeal carcinoma, supraglottic carcinoma, or carcinoma of the medial piriform sinus infiltrating the arytenoid cartilage or cricoarytenoid joint. A referred earache may occur, especially when nasopharyngeal tumors block the eustachian tube.⁵² Some patients are asymptomatic but present with a palpable neck mass. Most patients with squamous cell carcinoma are 50 to 70 years of age.⁵² Almost all patients (>95%) are moderate to heavy abusers of alcohol and tobacco or have a tumor related to herpes virus.⁵³

SQUAMOUS CELL CARCINOMA

Pathology

Squamous cell carcinomas represent 90% of malignant lesions involving the oropharynx and hypopharynx.^{6,53} Most of these tumors are keratinizing squamous cell carcinomas. In general, they occur in two macroscopic forms: (1) exophytic tumors that spread over the mucosa; and (2) infiltrative or ulcerative tumors that penetrate deeply into surrounding soft tissue, cartilage, and bone.⁷ Multiple primary lesions of the oral cavity, pharynx, esophagus, and lung are seen in more than 20% of patients.⁵² Because such a strong association exists between head and neck squamous cell carcinoma and esophageal carcinoma,^{54,55} a major goal of a preoperative radiologic study is to rule out a synchronous primary esophageal cancer. Between 1% and 15% of patients with head and neck squamous cell carcinoma subsequently develop squamous cell carcinoma of the esophagus.^{54,55}

Radiographic Findings

The radiographic findings of pharyngeal cancer include an intraluminal mass, mucosal irregularity, and impairment or loss of normal mobility or distensibility (Fig. 16-16).^{37,56-59} An intraluminal mass may be manifested radiographically by obliteration of the normal luminal contour, extra

Figure 16-11 *Candida pharyngitis.* Lateral view of the pharynx shows well-circumscribed plaques (open arrows) at the level of the epiglottis. Note laryngeal vestibule penetration (solid arrows) resulting from abnormal pharyngeal motility associated with this inflammatory pharyngitis. (From Rubesin SE: Pharynx. In Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

barium-coated lines protruding into the expected pharyngeal air column, a focal area of increased radiopacity, or a filling defect in the barium pool.^{37,38,56,59} Mucosal irregularity may be seen as abnormal barium collections resulting from surface ulceration or as a lobulated, finely nodular, or granular surface texture.⁵⁶ Asymmetrical distensibility is seen as flattening of the pharyngeal contour caused by fixation of structures by infiltrating tumor or by an extrinsic mass impinging on the pharynx.^{38,58,59}

Cross-sectional imaging studies are the examinations of choice for showing spread of tumor into the submucosa, intrinsic muscles, tissues extrinsic to the pharynx, and regional lymph nodes.⁶⁰ Computed tomography (CT) and MRI may occasionally reveal lesions (typically submucosal masses) that are not visible, even with modern endoscopes.

Specific Sites

Nasopharynx. Squamous cell carcinoma is the most common histologic type of nasopharyngeal malignant tumor. Many nasopharyngeal squamous cell cancers are undifferentiated tumors, and many have a reactive lymphoid stroma. The risk factors, age of presentation, and histologic type are more varied than those of the typical squamous cell carcinoma of the oropharynx and hypopharynx. In addition to alcohol and smoking abuse, poor ventilation, nasal balms, ingested carcinogens, and upper respiratory viruses such as the Epstein-Barr virus have been implicated as causative factors.⁶

Nasopharyngeal squamous cell carcinoma occurs at a relatively young age, with 20% of patients being younger than 30 years.⁶ Approximately 50% of patients complain of hearing loss because of eustachian tube involvement. About 50% of these patients are asymptomatic and present with a neck mass caused by cervical nodal metastases. Other signs and symptoms include nasal obstruction, epistaxis, pain,

Figure 16-12 *Scarring caused by lye ingestion.* **A.** On the lateral view, the tip of the epiglottis (arrow) appears truncated. **B.** On the frontal view, the epiglottis (white arrow) is located inferior to its normal position. A scar in the inferior portion of the left piriform sinus is seen as a fold of tissue (black arrow).

Figure 16-13 Retention cyst at the base of the tongue. Lateral view shows a smooth-surfaced hemispheric mass (arrow) protruding posteriorly from the base of the tongue.

headache, and damage to the fifth cranial nerve. The 5-year survival rate varies from 76% for patients with localized tumors to 10% to 20% for patients with cervical lymph node metastases.

MRI is the method of choice for evaluating tumors of the nasopharynx.⁶¹ The radiologist carefully searches for spread to the nasal cavity, sinuses, and cranial base, especially for cranial nerve involvement. Barium studies are used primarily to evaluate the symptoms of nasal regurgitation and voice changes caused by soft palate insufficiency and to rule out a synchronous esophageal tumor.

Palatine Tonsil. Squamous cell carcinoma of the palatine tonsil is the most common malignant tumor arising in the pharynx.⁶ Well-differentiated tumors are usually exophytic and easily seen on barium studies (Fig. 16-17).³⁷ Poorly differentiated tumors are frequently of the ulcerative infiltrative type and may be obscured on barium studies by the underlying nodular lymphoid tissue of the palatine tonsil.³⁸ Tonsillar tumors may spread to the soft palate, base of the tongue, and posterior pharyngeal wall. Approximately 50% of patients develop cervical nodal metastases.³⁷

Base of the Tongue. Squamous cell carcinomas of the base of the tongue are poorly differentiated lesions that often present as advanced lesions with nodal metastases.^{6,62} These tumors infiltrate deeply into the intrinsic and extrinsic muscles of the tongue. Lymph node metastases are seen ipsilaterally or contralaterally in more than 70% of patients. The 5-year survival rate is 20% to 40%.³⁷ Patients with small lesions are

Figure 16-14 Retention cyst. A smooth-surfaced, well-circumscribed mass (arrow) is seen in the region of the mucosa overlying the muscular process of the right arytenoid cartilage. This 2.5-cm mass was not detected on endoscopy. After a repeat endoscopic examination confirmed the presence of the lesion, surgery was performed and pathologic evaluation revealed a retention cyst lined by squamous epithelium. (From Rubesin SE, Glick SN: *The tailored double-contrast pharyngogram*. *Crit Rev Diagn Imaging* 28:133–179, 1988.)

often asymptomatic but present with enlarged cervical nodes. Initial results of diagnostic endoscopy may be negative.⁶³ Small or predominantly submucosal lesions may be hidden in the valleculae or the recess between the tongue and tonsil (glossotonsillar recess). Barium, MRI, or CT studies may be extremely helpful in detecting clinically occult lesions with nodal metastases.

Radiographically, an exophytic lesion appears as a polypoid mass projecting into the oropharyngeal air space.^{63,64} An ulcerated lesion appears as an irregular barium collection disrupting the expected contour of the base of the tongue. Nodules of tumor may spread to the palatine tonsil, valleculae, or pharyngoepiglottic fold. Occasionally, a deeply infiltrating, primarily submucosal lesion may be manifested by subtle asymmetric enlargement of the tongue base. A small plaque-like or ulcerative lesion can easily be missed on barium or endoscopic studies but can be detected on MRI or CT studies.

Supraglottic Region. Squamous cell carcinomas that affect the epiglottis, aryepiglottic folds, mucosa overlying the arytenoid cartilages, false vocal cords, and laryngeal ventricles are defined as supraglottic carcinomas. These poorly differentiated or undifferentiated tumors spread rapidly to the entire supraglottic region and pre-epiglottic space.³⁷ Exophytic lesions are more

Figure 16-15 Unsuspected soft palate carcinoma. An 80-year-old patient with dementia underwent an upper GI examination for epigastric pain. Nasal regurgitation was observed during the initial double-contrast swallow. Lateral spot image of the pharynx shows obliteration of the contour of the lower soft palate, which is replaced by a lobulated mass (solid arrows). Nodular mucosa in the tonsillar fossa (open arrow) indicates spread of the tumor into this region. (From Rubesin SE, Rabischong P, Bilaniuk LT, et al: Contrast examination of the soft palate with cross-sectional correlation. *RadioGraphics* 8:641–665, 1988.)

common (Fig. 16-18).^{57,65} Ulcerative lesions may deeply penetrate the tongue and valleculae and invade the pre-epiglottic space (Fig. 16-19).⁵⁷ These tumors may spread laterally to the pharyngoepiglottic folds and lateral pharyngeal walls. Only rarely do these tumors extend through the laryngeal ventricles into the true vocal cords. Cervical nodal metastases are seen in one third to one half of patients.^{37,65} The 5-year survival rate is approximately 40%.

Piriform Sinus. Squamous cell carcinomas of the piriform sinuses are advanced lesions that spread quickly and metastasize widely.⁵⁶ Metastases to cervical lymph nodes are seen in 70% to 80% of patients.³⁷ The 5-year survival rate is 20% to 40%.⁶³

Tumors involving the medial wall of the piriform sinus have a slightly better prognosis than lateral wall tumors⁶⁶ because medial wall tumors present early with hoarseness when they infiltrate the aryepiglottic fold, arytenoid and cricoid cartilages, and paraglottic space.⁵⁶ Tumors involving the lateral wall present later as a neck mass when they infiltrate the thyrohyoid membrane, thyroid cartilage, and soft tissues of the neck, including the structures of the carotid sheath.^{37,67}

Figure 16-16 Radiographic findings in pharyngeal carcinoma. A frontal view shows loss of the normal contour of the left piriform sinus. Obliteration of the contour indicates that the lateral and inferior piriform sinus has been replaced by a soft tissue mass (black arrows). The left aryepiglottic fold (white arrow) is enlarged and has a nodular surface, indicating tumor infiltration. The mucosa overlying the muscular process of the left arytenoid cartilage is enlarged (white arrowhead) and deviated medially, crossing the midline. Thus, the hypopharyngeal tumor involves the lateral hypopharyngeal wall, left arytenoid region, and left aryepiglottic fold. Barium coating the vocal cords results from abnormal epiglottic tilt on the left caused by tumor infiltration.

Radiographically, an early lesion may appear as a subtle area of mucosal irregularity (Fig. 16-20). Advanced lesions are typically seen as bulky exophytic masses (Fig. 16-21). Occasionally, infiltrative masses are seen.

Posterior Pharyngeal Wall. Squamous cell carcinomas of the posterior pharyngeal wall are typically large fungating lesions more than 5 cm in length (Fig. 16-22), often spreading vertically into the nasopharynx or cervical esophagus. Approximately 50% of patients have jugular or retropharyngeal lymphatic metastases, or both, at the time of diagnosis.⁵² The 5-year survival rate is approximately 20%.⁵² Posterior pharyngeal squamous cell carcinoma is the type of pharyngeal cancer usually associated with a synchronous or metachronous malignant lesion in the oral cavity, pharynx, or esophagus.

Postcricoid Area. Postcricoid squamous cell carcinomas are rare, except in Scandinavia.⁵⁶ In Scandinavia, primary postcricoid carcinomas may be associated with iron deficiency anemia and cervical esophageal webs, the Plummer-Vinson syndrome. In the United States, however, only a rare association has been found between iron deficiency anemia and malignant

Figure 16-17 Squamous cell carcinoma of the right palatine tonsil. **A.** Frontal view shows a large polypoid mass (arrows) protruding into the oropharynx. The right lateral wall of the tonsillar fossa has been obliterated. **B.** Lateral view shows a large tonsillar fossa mass (white arrows) with a central ulcer (open arrow). Tumor infiltration of the posterior pharyngeal wall is manifested by enlargement of the soft tissue space in this region (black arrows). The soft palate (S) is also widened and has an irregular contour. (From Levine MS, Rubesin SE: *Radio-logic investigation of dysphagia*. AJR 154:1157–1163, 1990.)

Figure 16-18 Polypoid squamous cell carcinoma of the epiglottis. **A.** Frontal view shows an enlarged, rounded epiglottic tip (open arrow) and an enlarged, nodular, left aryepiglottic fold (long white and black arrows). Note excessive pooling of barium in the valleculae. Laryngeal penetration has occurred, coating the laryngeal vestibule. This barium coating shows that the tumor has not spread to the lower right side of the epiglottis and right aryepiglottic fold (short white arrows). **B.** Lateral view shows a bulbous, enlarged, epiglottic tip (open arrow) and a large epiglottic mass (large arrows) extending down the aryepiglottic fold and along the anterior wall of the laryngeal vestibule. The lower portion of the laryngeal vestibule (small arrows) is not involved by tumor. (From Rubesin SE: *Pharynx*. In Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 16-19 Ulcerative squamous cell carcinoma of the epiglottis and base of the tongue. Frontal (A), lateral (B), and left posterior oblique (C) views show that the epiglottic tip and median glossoepiglottic fold have been destroyed and are not visualized. The normal vallecular contour is not seen. Instead, an irregular barium collection is seen in the base of the tongue, with deep penetration into the contour of the tongue (short arrows). The tumor is manifest by finely nodular mucosa at the base of the tongue and in the upper right aryepiglottic fold (open arrows), as well as on the upper laryngeal surface of the residual epiglottis (long arrow in B).

pharyngeal tumors. The pharyngoesophageal segment is usually involved by direct extension of squamous cell cancer of the piriform sinus, posterior pharyngeal wall, or cervical esophagus.⁵⁶ Radiographically, postcricoid carcinomas appear as annular infiltrating lesions that may extend into the lower hypopharynx or cervical esophagus (Fig. 16-23).³⁷ These annular lesions are best detected while the pharyngoesophageal segment is fully distended with barium on video recordings or rapid-sequence spot images obtained during swallowing.

LYMPHOMA

Lymphomas of the pharynx represent approximately 10% of malignant pharyngeal tumors.^{6,68} Almost all pharyngeal lymphomas are of the non-Hodgkin's type, arising from Waldeyer's ring (i.e., the adenoids, palatine tonsils, and lingual tonsil). Hodgkin's lymphoma involving the pharynx is rare, despite the fact that Hodgkin's lymphoma often begins in cervical lymph nodes.⁶⁹ Pharyngeal involvement occurs in only 1% to 2% of all patients with Hodgkin's lymphoma, even those with disseminated tumor.

Most patients with pharyngeal lymphoma are in the fifth to sixth decade of life. Approximately 50% of patients have cervical lymphadenopathy as the initial clinical finding.⁶⁸ Cervical

lymph nodes are involved in more than 60% of patients.⁶⁸ At the time of diagnosis, only 10% of patients have involvement of extranodal sites (lung and bones). Approximately 50% of patients have symptoms related to local pharyngeal involvement, including nasal obstruction, earache, sore throat, or a lump in the throat.

The most frequent pharyngeal locations of lymphoma are the palatine tonsil (40%-60% of patients),^{6,68} nasopharynx (18%-28%),⁶⁸ and base of the tongue (10%). Approximately 25% of tumors involve multiple sites. Bilateral involvement of the palatine tonsils occurs in 15% of pharyngeal lymphomas.⁶⁸ Lymphomas only rarely arise in the hypopharynx.

Pharyngeal lymphomas are manifested radiographically as lobulated masses involving the nasopharynx, palatine tonsil (Fig. 16-24), base of the tongue (Fig. 16-25), or a combination of these sites. The normal lymphoid follicular pattern of the base of the tongue or palatine tonsil may be effaced by these bulging submucosal masses.

RARE MALIGNANT TUMORS

Carcinoma of the Minor Salivary Glands

Benign and malignant tumors arise from the minor mucous salivary glands located deep to the epithelial layer of the

Figure 16-20 Squamous cell carcinoma of the lateral wall of the right piriform sinus. Frontal view shows obliteration of the right lateral wall of the piriform sinus. There is a large polypoid mass (long arrows) protruding into the hypopharynx. The tip of the epiglottis (short arrow) is spared. (From Rubesin SE, Glick SN: *The tailored double-contrast pharyngogram*. *Crit Rev Diagn Imaging* 28:133–179, 1988.)

Figure 16-21 Early squamous cell carcinoma of the right piriform sinus extending into the submucosa. Lateral view of the pharynx shows a flat area of nodular mucosa (open arrows) along the lateral wall of the right piriform sinus. (From Levine MS, Rubesin SE, Ott DJ: *Update on esophageal radiology*. *AJR* 155:933–941, 1990.)

Figure 16-22 Squamous cell carcinoma of the posterior pharyngeal wall. Lateral spot image of the pharynx shows a large fungating mass (arrows) on the posterior pharyngeal wall, extending from the level of the uvula to the level of the muscular processes of the arytenoid cartilages (a). Note evidence of pharyngeal dysfunction with pooling of barium in the valleculae (v), piriform sinus (p), and laryngeal vestibule (l). (From Rubesin SE, Glick SN: *The tailored double-contrast pharyngogram*. *Crit Rev Diagn Imaging* 28:133–179, 1988.)

pharynx. Minor salivary gland tumors constitute 20% of all salivary gland tumors and have diverse histologic features and a diverse clinical course. Of minor salivary gland tumors, 65% to 88% are malignant.⁷⁰ The most frequent malignant types are adenoid cystic carcinoma (35%), solid adenocarcinoma (22%; Fig. 16-26), and mucoepidermoid carcinoma (16%).⁷⁰ The most common pharyngeal location of minor salivary gland tumors is the soft palate. Palatal salivary gland tumors are manifested clinically by painless masses near the junction of the hard and soft palates. Palatal salivary gland tumors spread to the tongue, submandibular gland, lingual and hypoglossal nerves, and mandible. In contrast to squamous cell carcinoma, cervical metastases are relatively infrequent, occurring in approximately 25% of malignant lesions.⁷⁰ Adenoid cystic carcinoma has a particular propensity for perineural tumor spread.

Sarcoma

Malignant fibrous histiocytoma (Fig. 16-27) and synovial sarcomas of the pharynx are extremely rare.^{71,72} Most patients with synovial sarcoma are 20 to 40 years of age and complain of a painless neck mass. At initial diagnosis, synovial sarcomas appear radiographically as large bulky tumors involving the

Figure 16-23 Squamous cell carcinoma of the postcricoid region. **A.** Lateral spot image obtained during swallowing shows a finely lobulated contour of the anterior and posterior walls of the pharyngoesophageal segment (arrows). **B.** Lateral spot image of the pharyngoesophageal segment during phonation shows an ulcerated mass. The central ulcer crater (large white arrow) is filled with barium. The mass is seen as a filling defect in the barium pool (black arrows) and as an irregular contour of the posterior pharyngeal wall (medium white arrows). The mass also causes a smooth extrinsic impression on the posterior wall of the trachea (small white arrows).

larynx, pharynx, and soft tissues of the neck.⁷² A clue that a bulky pharyngeal tumor is a sarcoma, not a squamous cell carcinoma, is marked enhancement during a CT or MRI examination of the neck.⁷¹

Cartilaginous Tumors

Primary cartilaginous tumors of the pharynx are extremely rare. The pharynx may be invaded secondarily by cartilaginous tumors (e.g., chondroma, osteochondroma, chondrosarcoma) arising in the larynx.⁷³ Cartilaginous tumors of the larynx are seen mainly in the fourth to sixth decade of life. Patients complain of hoarseness, poor voice, and dysphagia. Chondroid tumors usually arise from the cricoid cartilage.

Radiographically, a smooth-surfaced mass is usually seen in the posterior lamina of the cricoid cartilage, compressing and distorting the lower hypopharynx and pharyngoesophageal segment. Stippled calcification is seen in a central or peripheral location in more than 80% of patients.⁶

Kaposi's Sarcoma

Kaposi's sarcoma may arise anywhere in the GI tract in patients with AIDS. Kaposi's sarcoma involving the pharynx may cause dysphagia or odynophagia.⁷⁴ Radiographically, Kaposi's sarcoma

may be manifested by multiple small nodules or plaque-like lesions, small submucosal masses with or without central ulceration, or larger, bulky polypoid masses.⁷⁴

Pharyngeal Damage from Radiation

Radiation therapy may be used as a primary or adjunctive form of treatment for pharyngeal tumors such as squamous cell carcinoma and lymphoma. The pharynx is included within the radiation portal during irradiation of tumors of the larynx and cervical lymph nodes. In the past, the pharynx was also included in the radiation portal during treatment of thyrotoxicosis or tuberculous lymphadenitis.⁷⁵

Acute mucositis and edema occur early during the course of radiotherapy. Epithelial necrosis and ulceration result in a fibrinous exudate.⁷⁶⁻⁷⁸ Submucosal inflammation also occurs early. Over time, the mucosa atrophies and submucosal fibrosis may occur.⁷⁶ Most chronic radiation damage results from vascular changes, with thrombosis and fibrosis of capillaries and lymphatics and subintimal fibrosis and hyalinization of veins and arteries. Vascular damage leads to atrophy of the skin and to fibrosis of subcutaneous tissues, submucosal tissues, and muscle.⁷⁹ The most frequent localization of persistent edema is

Figure 16-24 Non-Hodgkin's lymphoma of the palatine tonsil. A large lobulated mass is seen in the tonsillar fossa (arrows). The uvula (u) is identified.

in the glottis and mucosa overlying the arytenoid cartilages. Severe complications such as life-threatening osteomyelitis and chondronecrosis may occur.

Five to 10 days after initial radiotherapy, the patient may complain of local discomfort, hoarseness, dryness, dysphagia, or a lump in the throat. The peak occurrence of symptoms occurs near the end of the typical 6-week course of radiation treatment. Most symptoms gradually subside 2 to 6 weeks after cessation of radiotherapy.⁷⁷ However, a substantial number of patients have persistent symptoms. For example, 15% of patients have persistent edema after radiotherapy for carcinoma of the vocal cord.⁸⁰ If the parotid or other salivary glands have been damaged, xerostomia may cause persistent dysphagia. Persistent edema may suggest a serious underlying complication such as persistent carcinoma or the development of osteomyelitis or chondronecrosis.⁸⁰⁻⁸² Approximately 50% of patients with persistent edema have recurrent or persistent tumor.⁸⁰

The radiographic changes of radiation damage are seen in almost all patients after radiation therapy, with or without surgery.⁸³ Spot images typically show that the epiglottis and aryepiglottic folds are diffusely and smoothly enlarged (Fig. 16-28).^{38,84,85} The valleculae may be flattened, and the mucosa overlying the muscular processes of the arytenoid cartilages may be elevated. Soft tissue atrophy seen with chronic radiation change is manifested as a small soft palate and as loss of the muscular soft tissue between the barium-coated posterior pharyngeal wall and vertebral bodies of the cervical spine. Edema

Figure 16-25 Lymphoma of the base of the tongue and epiglottic tip. Lateral view of the pharynx shows a large, lobulated mass involving the base of the tongue (large arrows) and tip of the epiglottis (small arrows). Note that the normal contours of the valleculae have been obliterated.

from radiation may be asymmetric, especially in the region of the original tumor. The most frequent dynamic findings are abnormal epiglottic tilt and poor closure of the laryngeal vestibule, resulting in laryngeal penetration, and pharyngeal paresis, resulting in stasis in the piriform sinuses, with the potential for overflow penetration.⁸³ Any surface irregularity on a post-radiation pharyngogram should suggest the possibility of persistent cancer, although radiation-induced ulceration may produce identical radiographic findings.^{2,84}

Postoperative Pharynx

The radiologist frequently studies the pharynx in the early and remote postoperative periods, testing a patient's ability to swallow and looking for complications. Ideally, the surgeon provides a clear description of the postoperative anatomy to the radiologist and states what information needs to be obtained from the postoperative pharyngogram. In reality, the radiologist must be familiar with the numerous operations performed for a wide variety of pharyngeal tumors, Zenker's diverticulum, and cricopharyngeal achalasia. The radiologist must also have a working knowledge of the spectrum of postoperative complications associated with these various procedures (Table 16-1).⁸⁶

TOTAL LARYNGECTOMY

Total laryngectomy is usually performed for advanced malignant tumors of the larynx, subglottic cancers, and small

Figure 16-26 Adenocarcinoma of the minor salivary glands. The epiglottic tip (*long arrow*) is apposed to the base of the tongue, and its vallecular surface is ulcerated. The valleculae are obliterated and filled by a lobulated tumor (*short arrows*) arising from the tongue base. This adenocarcinoma is radiographically indistinguishable from a typical squamous cell carcinoma of the base of the tongue. The tumor presumably arose in minor salivary gland tissue.

Figure 16-27 Malignant fibrous histiocytoma of the pharynx. Lateral view of the pharynx shows a 3-cm relatively smooth mass (*arrows*) protruding from the posterior wall of the upper hypopharynx. The surface is finely nodular anteriorly. Barium in the laryngeal vestibule and trachea resulted from poor closure of the laryngeal aditus when the epiglottis (E) was unable to tilt posteriorly.

Figure 16-28 Radiation changes in the pharynx. **A.** Frontal view of the pharynx shows smooth, bulbous enlargement of the epiglottis (*large black arrow*) and flattening of the valleculae (*left vallecula, arrowhead*). Abnormal pharyngeal motility results in laryngeal penetration. Barium coating the laryngeal vestibule demonstrates enlargement of the epiglottis, wide aryepiglottic folds (*small black arrows*), elevation of the mucosa overlying the muscular process of the arytenoid cartilages (*white arrow*), and even edema of the false vocal cords (f). **B.** Lateral view of the pharynx shows smooth, bulbous enlargement of the epiglottis (*large arrow*) and elevation of the mucosa overlying the muscular processes of the arytenoid cartilages (*small arrow*).

TABLE 16-1
Common Postoperative Complications

Stage	Voice-Sparing Procedure	Laryngectomy
Early postoperative period	Wound breakdown	Wound breakdown*
	Fistula formation*	Fistula formation*
Late postoperative period	Abscess (wound or fistula)	Abscess (wound or fistula)
	Aspiration, pneumonia*	Constrictor dysfunction*
	Airway obstruction (edema)	Tongue dysfunction (partial resection, immobility; rarely, hypoglossal nerve damage)*
	Hematoma	Hematoma
	Mediastinitis	Mediastinitis
	Thoracic duct or carotid injury from radical neck dissection	Thoracic duct or carotid injury from radical neck dissection
	Hoarseness	Stricture*
	Aspiration*	Constrictor dysfunction*
	Recurrent tumor*	Recurrent tumor*
	Laryngeal stenosis*	Stomal stenosis
	Velopharyngeal incompetence*	Stomal tumor recurrence
	Failure of flap graft	Failure of flap graft or jejunal graft
		Hypothyroidism
		Hypoparathyroidism
		Abnormal vocalization*

*Pharyngography is helpful for evaluation.

carcinomas of the low tongue base and for failed irradiation or voice-conserving surgery for laryngeal cancer.^{87,88} Early glottic or supraglottic cancers are often treated by radiation therapy, endoscopic removal, or partial laryngectomy.⁸⁹ Cancers of the piriform sinuses, lateral and posterior pharyngeal walls, and postcricoid region are treated by total laryngectomy with partial pharyngectomy or laryngopharyngectomy, depending on the degree of retropharyngeal invasion.

During total laryngectomy, the larynx is removed, along with the epiglottic, thyroid, cricoid, and paired arytenoid cartilages. The hyoid bone may be removed or spared. Resection of the epiglottis, aryepiglottic folds, arytenoid cartilages, and anterior walls of the piriform sinuses results in the creation of a large gap in the anterior wall of the hypopharynx. Total laryngectomy also disrupts most of the muscles of the pharynx. The suprahyoid muscles (mylohyoid, geniohyoid, hyoglossus, and stylohyoid) and infrahyoid muscles (thyrohyoid, sternohyoid, sternothyroid, and omohyoid) are transected. The thyropharyngeus and cricopharyngeus are detached from their lateral origins on the thyroid and cricoid cartilages, respectively. A permanent tracheostoma is necessary. In some patients, the ipsilateral thyroid gland and its accompanying parathyroid glands are excised.

The gap in the anterior wall of the pharynx is closed by approximating the residual pharyngeal mucosa. The constrictor muscles may be joined anteriorly as an additional buttressing layer. A myocutaneous or free flap may be necessary to form the neopharyngeal tube if there is insufficient mucosa. A neck dissection may also be performed.

Radiographically, the normal neopharyngeal tube resembles an inverted cone with a smooth mucosal surface (Fig. 16-29).⁸⁷ On lateral views, the anterior wall of the neopharyngeal tube lies just below the skin of the neck, and the posterior wall of the tube abuts the vertebral column. On frontal views, the tube is within 0.5 cm of the midline.⁸⁹ The epiglottis, aryepiglottic folds, and extrinsic mass of the larynx on the

hypopharynx are no longer present. The hyoid bone may also be absent. At the closure site of the base of the tongue and anterior neopharyngeal tube, the contour may be angulated or sacculated. These postoperative sacculations at the tongue base are normal and resemble valleculae—hence, the term *pseudovalleculae*. A fold of tissue courses from each posterolateral wall of the oropharynx to the new base of the tongue, superficially resembling an epiglottis—hence, the term *pseudoepiglottis*.

The most common complication in the early postoperative period is the formation of a pharyngocutaneous fistula, occurring in 6% to 21% of patients (see Table 16-1).^{87,90,91} Fistulas develop at sites of mucosal closure, including the junction of the neopharyngeal tube with the tongue base, anterior aspect of the neopharyngeal tube (Fig. 16-30), margin of the flap (if one is used), and near the tracheal stoma. It is unknown whether radiation therapy increases the risk of fistula formation.⁹² Fistulas may end blindly in the subcutaneous tissue or extend to the skin and, rarely, may involve the carotid sheath. Most patients have signs of fistula formation within 10 to 14 days after surgery, including fever, wound erythema, swelling, and increased drainage from the wound.⁹³ Some patients with fistulas are asymptomatic. Most fistulas close spontaneously if feeding is delayed. The development of a fistula in the late postoperative period should suggest recurrent tumor. Radiographically, fistulas appear as contrast-filled tracks or collections arising from the anterior pharyngeal wall or base of the tongue.

Dysphagia is the most common symptom in the remote postoperative period. This symptom may be caused by benign strictures, retracted thyropharyngeal or cricopharyngeal muscle, or recurrent tumor. Some patients have no symptoms because they compensate for luminal narrowing by changing their diet and chewing patterns. Radiographically, benign strictures have a smooth contour and mucosal surface. Long (>3 cm) symmetric strictures involving a large portion of the neopharyngeal

Figure 16-29 Total laryngectomy. **A.** Frontal view of the neopharynx shows a featureless tube that tapers distally. The tube is wider than 5 mm in each direction and the mucosa is smooth. The neopharyngeal tube is in the midline. **B.** Lateral view also shows a tubular structure that tapers inferiorly. Just behind the junction of the tongue and neopharyngeal tube, a tubular radiolucency (arrows) curves superiorly toward the lateral mid-oropharyngeal wall. This is a pair of folds created surgically on each side of the lateral pharyngeal wall. Because these folds mimic the course of the epiglottis, they have been termed a *pseudoepiglottis*. The hyoid bone, valleculae, epiglottis, and piriform sinuses are missing. (From Rubesin SE, Eisele DW, Jones B: *Pharyngography in the postoperative patient*. In Jones B [ed]: *Normal and Abnormal Swallowing. Imaging in Diagnosis and Therapy*, 2nd ed. New York, Springer, 2003, pp 167–204.)

Figure 16-30 Leak after total laryngectomy. Lateral view of the neopharynx after the patient swallows water-soluble contrast shows a linear contrast collection (*short arrow*) just anterior to the anterior wall of the neopharyngeal tube. The collection arises from a short track (*long arrow*). A nasogastric tube is in place. A tracheostomy tube is seen inferiorly. (From Rubesin SE: *Pharynx*. In Levine MS, Rubesin SE, Laufer I [eds]: *Double Contrast Gastrointestinal Radiology*, 3rd ed. Philadelphia, WB Saunders, 2000, pp 61–89.)

tube are usually the sequelae of radiation therapy or insufficient mucosa at the time of closure (Fig. 16-31).⁸⁷ Short (5 mm) weblike narrowings usually form at the upper or lower end of the closure line and are usually the sequelae of infection or fistula formation (Fig. 16-32).⁸⁷ Although some benign strictures have irregular contours, the presence of mucosal nodularity in the region of a stricture should suggest recurrent tumor. Deviation of the neopharyngeal tube from the midline is uncommon and should also suggest recurrent tumor.

After total laryngectomy, most of the muscles of the pharynx lose their normal bony or cartilaginous attachments and are partially or totally denervated. Dysphagia may result from abnormal muscular contraction. The thyropharyngeus and cricopharyngeus muscles, in particular, may not participate in a coordinated contraction wave with the spared superior constrictor muscle. Radiographically, abnormal inferior constrictor contraction is manifested by a smooth extrinsic mass impression on the posterior wall of the neopharyngeal tube (Fig. 16-33). Unlike recurrent tumor, this impression changes in size, shape, and position during swallowing. Stasis of barium and dilation of the oropharynx above a prominent cricopharyngeus are clues that postoperative dysphagia may be related to abnormal muscular contraction.

Foreign body impactions often occur in the neopharyngeal tube. Patients with head and neck cancers frequently have poor dentition or have had teeth removed before radiotherapy. These patients may have difficulty chewing vegetables and meats. As a result, solid food may become lodged in normal areas of postoperative sacculation at the base of the tongue, in a neopharynx that contracts poorly, or above strictures (Fig. 16-34).

Recurrent squamous cell carcinoma usually develops within 2 years after laryngectomy.⁹³ Radiographically, recurrent tumor may be manifested by a large (>1.5 cm) mass with a nodular or ulcerated surface or as a stricture with an irregular contour and irregular mucosal surface.^{2,86,94} The neopharynx may be deviated more than 1 cm from the midline, with narrowing of the neopharyngeal tube at the site of maximal deviation.⁸⁷

The hypoglossal nerves that lie superficially on the hyoglossus muscle may be damaged during surgery. Abnormal tongue motion may result from hypoglossal nerve damage, partial glossectomy, or postoperative scarring. Complications involving the tracheal stoma include stomal stenosis and recurrent tumor. Voice rehabilitation may be difficult because of a retracted cricopharyngeus, malpositioned tracheoesophageal voice prosthesis, gastroesophageal reflux, or esophageal motility disorder.

PHARYNGOLARYNGECTOMY

Resection of the larynx and hypopharynx may be required if cancer involves the posterior pharyngeal wall, postcricoid region, or large portions of a piriform sinus. The gap between the oropharynx and cervical esophagus may be bridged by a free jejunal graft or by a gastric pull-through.^{95,96} A defect in the anterolateral neopharyngeal wall may also be closed by a myocutaneous flap (pectoralis major or trapezius), free flap (radial forearm), or cutaneous skin flap (thigh).^{96,97}

Radiographically, flaps are atonic segments that form a portion of the walls of the pharynx. These flaps often protrude as masslike lesions into the expected lumen of the neopharynx. Complications of flaps include ischemic necrosis (Fig. 16-35) and leaks. Accumulation of hair and cutaneous debris on the luminal surface of a cutaneous flap (termed the *hirsute pharynx*) can cause mucosal nodularity and partial obstruction to the flow of liquids (Fig. 16-36).

In creating a jejunal free flap, a segment of proximal jejunum and its vascular arcade are autotransplanted into the neck and placed in a peristaltic direction. Jejunal contractions do not aid in bolus propulsion, however, because they occur at a slow rate of three contractions per minute and are not coordinated with swallowing. Clearance of the bolus from jejunal grafts is accomplished by gravity and pressure generated by tongue base push.⁹⁸ Complications of jejunal free grafts include fistula formation and ischemia. A normal jejunal free flap radiographically appears as a tubular segment of bowel, with a thin valvulae conniventes. No acute narrowing, angulation, or tethering of the tube should be seen.

ESOPHAGEAL SPEECH

Vocalization after total laryngectomy is accomplished by a buccal, oropharyngeal, or esophageal speech or voice prosthesis placed in a surgically created tracheoesophageal fistula. During esophageal speech, the patient swallows air into the esophagus

Figure 16-31 Stricture after total laryngectomy. Frontal (A) and lateral (B) views of the neck show diffuse narrowing of the neopharyngeal tube (long arrows). An even tighter weblike area of narrowing (small arrow) is seen proximally. Long strictures are usually attributed to radiation therapy or insufficient tissue to close the neopharynx. (From Rubesin SE: *Pharynx*. In Levine MS, Rubesin SE, Laufer I [eds]: *Double Contrast Gastrointestinal Radiology*, 3rd ed. Philadelphia, WB Saunders, 2000, pp 61–89.)

Figure 16-32 Short stricture after total laryngectomy. Lateral view shows a short circumferential stricture (*long arrow*) of the upper neopharyngeal tube. The anterior wall is undulating, caused by scarring. A pseudoepiglottis is identified (*short arrows*).

Figure 16-33 Incomplete opening of cricopharyngeus after total laryngectomy. Lateral view of the neck shows a smooth-surfaced protrusion (*arrows*) into the posterior wall of the lower neopharyngeal tube. During fluoroscopy, this indentation changed in size and shape because of prominence of the lower portion of the thyropharyngeus and cricopharyngeus.

and then expels the air through the cricopharyngeus into the neopharynx and oral cavity. The pharyngoesophageal segment narrowing varies in length and diameter during normal esophageal speech. Rapid change of configuration of the cricopharyngeus replaces the vibrations of the resected true vocal cords.

Pharyngoesophagography helps determine the causes of failure to attain esophageal speech.⁹⁹ Fixation and marked narrowing of the pharyngoesophageal segment may prevent esophageal speech.¹⁰⁰ Patients who have adequate quality of speech but diminished loudness may have a flaccid or strictured pharyngoesophageal segment.

NECK DISSECTION

A unilateral or bilateral neck dissection may be performed, depending on the initial location and size of the primary tumor and presence of clinically or radiographically suspected lymph node metastases. The submandibular gland, internal jugular vein, spinal accessory nerve, hypoglossal nerve, external carotid artery, and sternocleidomastoid muscle may be preserved or resected.

A chylous collection may form in the left lower neck because of thoracic duct damage or in the right lower neck because of accessory duct damage. Damage or resection of the hypoglossal nerve may lead to tongue dysfunction. Shoulder dysfunction may result from damage or resection of the spinal accessory nerve supplying the trapezius muscle.¹⁰¹

VOICE-SPARING PROCEDURES

Horizontal (Supraglottic) Laryngectomy

During supraglottic laryngectomy, the epiglottis, aryepiglottic folds, and false vocal cords are removed. The thyroid cartilage is transected at the level of the laryngeal ventricle.¹⁰² The voice is conserved because the true vocal cords and arytenoid cartilages are spared. In some patients, one arytenoid cartilage and part of the medial wall of the piriform sinus on the side of the tumor are resected.¹⁰³ The hyoid bone may be spared or partially or fully resected. A cricopharyngeal myotomy may be performed.¹⁰³ The remaining portion of the thyroid cartilage and larynx are pulled up to the base of tongue (or hyoid, if this structure is spared). The free anterior edge of the piriform sinus is pulled anteromedially, creating a fold superior to the vocal cord.¹⁰³

Radiographically, the epiglottis and aryepiglottic folds are absent (*Fig. 16-37*). Barium penetrating the remaining larynx outlines the true vocal cords. On lateral views, the vocal cords lie just inferior to the tongue base. Barium etches the mucosa overlying the muscular processes of the arytenoid cartilages. The folds of the piriform sinus tissue that have been pulled superior to the vocal cords are outlined by barium, termed *pseudocords*.¹⁰² The mucosa at the junction between the tongue base and true vocal cords may appear nodular. On frontal

Figure 16-34 Foreign body impaction above stricture after total laryngectomy. Oblique view of the lower neck shows a 1-cm, finely lobulated, radiolucent filling defect (open arrows) in the lower neopharyngeal tube trapped above a 3-mm-long by 1- to 2-mm-diameter stricture (large arrow). This foreign body proved to be a piece of meat. A voice prosthesis is identified (arrowheads).

Figure 16-35 Partial breakdown of free flap. Oblique view shows numerous barium-filled tracks (arrows) extending into the interstices of the flap. (From Rubesin SE, Eisele DW, Jones B: *Pharyngography in the postoperative patient*. In Jones B [ed]: *Normal and Abnormal Swallowing. Imaging in Diagnosis and Therapy*, 2nd ed. New York, Springer, 2003, pp 167–204.)

views, the barium-etched vocal cords and arytenoid cartilages are seen. If one arytenoid cartilage has been removed, the neolarynx appears asymmetric. A concomitant neck dissection may result in ipsilateral flattening of the lateral pharyngeal wall.

Complications in the immediate postoperative period include aspiration, fistula formation, and airway obstruction caused by postoperative edema. A Zenker's diverticulum may develop (see Fig. 16-37). Edema and fibrosis are manifested radiographically by smooth, symmetric or asymmetric enlargement of the mucosa overlying the muscular processes of the arytenoid cartilages. Fistulas develop in approximately 15% of patients.¹⁰³ The most common complications in the late postoperative period are aspiration in over 40% of patients and recurrent tumor in up to one third of patients.¹⁰⁴ Recurrent tumor is manifested radiographically by a focal mass with a nodular mucosal surface.

Vertical Laryngectomy

Early glottic carcinomas may be treated by endoscopic surgery, radiotherapy, and open surgical procedures. Cancers of the anterior portion of the true vocal cords and anterior commissure can be treated by a variety of surgical procedures, including cordectomy, vertical partial laryngectomy, and vertical hemilaryngectomy.¹⁰⁵

Cordectomy. Cancers localized to the true vocal cord or cancer with limited extension to the contralateral anterior commissure may be treated by cordectomy.¹⁰⁶ The vocal cord and internal perichondrium of the thyroid cartilage are resected.

Vertical Partial Laryngectomy. Vertical partial laryngectomy is used to treat glottic cancers with local extension to the arytenoid and floor of the laryngeal ventricle or cancers that occur after radiotherapy.¹⁰⁷ The cancerous vocal cord and approximately one third of the thyroid cartilage on the side of the tumor are resected.¹⁰⁷ The epiglottis is preserved, and its base is reattached. The false vocal fold on the side of the tumor may be reattached to the remaining ipsilateral thyroid cartilage.

Vertical Hemilaryngectomy. The true vocal cord, false vocal cord, arytenoid cartilage, and thyroid cartilage on the side of the tumor are resected. This procedure is often complicated by laryngeal stenosis and aspiration.

The radiographic findings associated with the various forms of vertical laryngectomy depend on the extent of surgery. If a cordectomy has been performed and no laryngeal penetration occurs, the pharynx may appear relatively normal.¹⁰⁸ If a complete vertical hemilaryngectomy has been performed, aspiration usually occurs. The true and false vocal cords and arytenoid that

Figure 16-36 Hirsute neopharynx. Oblique view of the neck shows that the mucosa of the neopharynx is diffusely nodular (open arrows), which was caused by barium coating the skin and hair of this radial forearm flap. (From Rubesin SE, Eisele DW, Jones B: *Pharyngography in the postoperative patient*. In Jones B [ed]: *Normal and Abnormal Swallowing. Imaging in Diagnosis and Therapy*, 2nd ed. New York, Springer, 2003, pp 167–204.)

have been removed will be missing from the radiographs. The preserved contralateral true and false vocal cords will be etched by barium (Fig. 16-38).

A combination of endoscopy, cross-sectional imaging, and barium studies is helpful in the diagnosis of recurrent tumor.^{108,109} Recurrent tumor may be manifested radiographically by narrowing and irregularity of the residual laryngeal vestibule or subglottic region. However, postoperative deformity caused by edema or granulation tissue can mimic tumor recurrence.

SURGERY FOR TONGUE AND OROPHARYNGEAL CANCERS

Glossectomy

Surgical approaches to the tongue depend on the size, location, and spread of the primary tumor.¹¹⁰ Small lesions of the anterior tongue may be resected via a transoral approach. Larger lesions may require exposure via a mandibulotomy. Segmental mandibular resection is performed for lesions involving the mandible. Small lesions of the posterior tongue may be operated on via a transhyoid approach.

Large tumors of the posterior tongue may require near-total or total glossectomy. This procedure may include resection of tissue in the floor of the mouth, retromolar trigone, and lateral pharyngeal wall. A skin graft, tissue flap, or microvascular free flap can be used.¹¹¹ A concomitant cricopharyngeal myotomy may be performed as a drainage procedure. Approximately one third to one half of the tongue can be removed without resulting in significant swallowing disability.¹¹²

During a barium swallow, the radiologist evaluates collection and manipulation of the bolus by the residual tongue, stasis in the oral cavity, and premature spillage of the bolus into the hypopharynx. Abnormal tongue motion may reflect loss of tongue volume, adhesions, or damage to the hypoglossal nerve. A large proportion of the bolus may remain in the oral cavity. Abnormal elevation of the pharynx and larynx and abnormal epiglottic tilt may result from surgical transection of various suprahyoid muscles. Aspiration is detected in 10% to 33% of patients after total glossectomy.¹¹³ Postoperative deformity of the tongue is the norm (Fig. 16-39) but is difficult to distinguish from recurrent tumor. The diagnosis of recurrent tumor is best made by a combination of direct visualization and cross-sectional imaging.

Malignant Oropharyngeal Lesions

Surgical approaches to the oropharynx include the transoral route, lip splitting with or without mandibulotomy, mandibulotomy, or a transcervical approach. A neck dissection is often concomitantly performed. Surgical defects may be filled with a skin graft, myocutaneous flap, or free flap.¹¹⁴

Portions of the palate may be resected for primary squamous cell carcinoma, lymphoma, or minor salivary gland tumors or for contiguous tumors of the tonsil or retromolar trigone region secondarily invading the palate. Soft palate or tonsillar resection may result in hypernasal speech or nasal regurgitation. Partial palatotomy may also cause premature spillage of the bolus from the oral cavity into the oropharynx, resulting in poor timing of the swallow, with subsequent laryngeal penetration. Postoperative defects in the palate may result in an oronasal or sinonasal fistula. Flap or graft breakdown may result in an orocutaneous or pharyngocutaneous fistula. If the tongue base has been partially removed or is fixed by adhesions, the patient may have difficulty chewing or swallowing.

TRACHEOSTOMY

Patients with a tracheostomy (with or without laryngectomy) may develop dysphagia or aspiration caused by postoperative changes in the soft tissues of the neck, resulting in tethering of the trachea and pharynx, with subsequent diminished laryngeal and pharyngeal elevation.^{111,115} The presence of a tracheostomy may also result in poor coordination of laryngeal closure, with resultant aspiration during swallowing. A tracheostomy may also cause desensitization of the cough reflex.

SURGERY FOR ZENKER'S DIVERTICULUM AND PHARYNGEAL POUCHES

Various endoscopic and surgical procedures may be performed for treatment of Zenker's diverticulum. Some procedures alter

Figure 16-37 Zenker's diverticulum developing after horizontal hemilaryngectomy for epiglottic carcinoma. A. Lateral view of the pharynx shows that the hyoid bone, valleculae, epiglottis, and aryepiglottic folds are missing. Aspirated barium coats the true vocal cords (V) and anterior commissure (short arrow) that have been pulled up to the base of the tongue. The arytenoids (long arrows) are markedly elevated. The pharyngoesophageal segment is elevated, now opposite the anterior commissure. There is a Zenker's diverticulum (Z) and a prominent cricopharyngeal bar (arrowhead) that were not seen on preoperative images. **B.** Frontal view shows the prominent masslike arytenoids (white arrows). Folds of tissue arising from the lateral pharyngeal wall (right lateral fold identified by black arrow) have been pulled medially to cover the true vocal cords. The Zenker's diverticulum is a 1.5-cm midline ovoid barium collection (Z). (From Rubesin SE, Eisele DW, Jones B: *Pharyngography in the postoperative patient*. In Jones B [ed]: *Normal and Abnormal Swallowing. Imaging in Diagnosis and Therapy*, 2nd ed. New York, Springer, 2003, pp 167–204.)

Figure 16-38 Vertical hemilaryngectomy. A. Frontal view shows that the right false (f) and right true (t) vocal cords remain. The presence of barium in the right vallecula (V) indicates that at least part of the epiglottis has been preserved. In contrast, the absence of the left vallecula indicates that the left side of the epiglottis has been resected. The left true and false vocal cords and left aryepiglottic fold are missing and have been resected. The remaining portion of the left side of the hypopharynx is dilated with barium stasis inferiorly in the pharyngoesophageal segment. **B.** Lateral view shows the epiglottic tip (E) and right vallecula (V). The anterior commissure is coated with aspirated barium, and one vocal cord (t) and arytenoid (arrow) remain. A kissing artifact is seen in the lower hypopharynx.

Figure 16-39 Partial glossectomy. A large barium-coated defect (black arrows) is seen at the tongue base. This defect and associated tongue dysfunction resulted in premature spill of the bolus into the oropharynx. The contralateral portion of the base of the tongue is intact (white arrow). It is impossible to determine whether there is recurrent tumor in the nodular tissue lining the tongue defect. Radiation-induced, smooth-surfaced enlargement of the soft palate (S) and epiglottis (E) is seen. Nasal regurgitation results in barium coating the superior surface of the soft palate. Soft palate elevation is abnormal because a gap remains between the soft palate and posterior pharyngeal wall, despite phonation. Passavant's cushion (open arrow) is demonstrated. Abnormal soft palate elevation may have resulted from scarring related to surgery or prior radiation therapy. (From Rubesin SE, Eisele DW, Jones B: *Pharyngography in the postoperative patient*. In Jones B [ed]: *Normal and Abnormal Swallowing. Imaging in Diagnosis and Therapy*, 2nd ed. New York, Springer, 2003, pp 167–204.)

the prominent cricopharyngeus, whereas others involve the diverticulum itself. The most successful procedure combines diverticulectomy with cricopharyngeal myotomy.

Endoscopic dilation of the prominent cricopharyngeus has been performed¹¹⁶ but is often unsuccessful because the upper esophageal sphincter is not damaged enough to improve hypopharyngeal clearance and because the pouch is left intact. Surgical cricopharyngeal myotomy alone also has a poor success rate.¹¹⁷

Transection of the cricopharyngeus may be performed endoscopically in debilitated and older patients who are poor operative candidates.¹¹⁸ The anterior lip of a specially designed endoscope is placed into the lumen of the pharyngoesophageal segment, and the posterior lip of the endoscope is inserted into the diverticulum.¹¹⁹ The endoscopist then divides the posterior

wall of the pharyngoesophageal segment between the lumen of the pharyngoesophageal segment–cervical esophagus and the lumen of the Zenker's diverticulum. The Zenker's diverticulum is left intact, but the prominent cricopharyngeus is transected. On a postoperative pharyngogram, the Zenker's diverticulum that remains intact should have less barium filling because there is improved drainage through an opened pharyngoesophageal segment. The barium-air level in the diverticulum should be lower in comparison to that in preoperative studies. The pharyngoesophageal segment should also open to a greater degree than was seen preoperatively.

Diverticulopexy is a surgical procedure performed in high-risk patients that avoids opening the pharynx. The apex of the Zenker's diverticulum is suspended from the prevertebral fascia superior to the diverticulum.^{120,121} A cricopharyngeal myotomy is performed. Although the diverticulum may partially fill during swallowing, it drains through the damaged cricopharyngeus, diminishing the risk of aspiration.

The most successful approach for the treatment of Zenker's diverticulum is diverticulectomy with cricopharyngeal myotomy. An extended myotomy is performed, including division of the lowermost thyropharyngeus. The Zenker's diverticulum is excised without removing the mucosa of the pharyngoesophageal segment.¹²⁰ During postoperative pharyngography, the Zenker's diverticulum should not be seen. The pharyngoesophageal segment should open widely. In one series, however, 3 of 13 patients had a continued saclike outpouching at the site of surgical excision.¹²² Postoperative pharyngography may demonstrate unsuspected leaks and a characteristic beaklike postoperative deformity.¹²²

CRICOPHARYNGEAL MYOTOMY

Cricopharyngeal myotomy is used as an isolated drainage procedure in patients with an abnormally functioning pharyngoesophageal segment caused by a global pharyngeal motor disorder or Zenker's diverticulum.^{121,123} Cricopharyngeal myotomy facilitates drainage from a neuromuscularly impaired pharynx, as does pyloroplasty in patients who develop abnormal gastric emptying because of vagotomy. Cricopharyngeal myotomy is not indicated in patients with globus symptoms alone.¹²¹ Because the upper esophageal sphincter normally prevents reflux of esophageal contents into the pharynx, surgical destruction of the sphincter can sometimes lead to aspiration of esophageal contents into the lungs. The surgeon therefore balances the risk of aspiration caused by pharyngeal stasis in an untreated patient with a neuromuscularly compromised pharynx with the risk of aspiration of esophageal contents from a cricopharyngeal myotomy. Given the operative risks of cricopharyngeal myotomy, some physicians have been injecting botulinum toxin into the cricopharyngeus as an alternative form of treatment for ameliorating symptoms.

After cricopharyngeal myotomy, pharyngography should demonstrate less stasis of barium in the hypopharynx. The cricopharyngeal bar should be absent, and there should be decreased or no luminal narrowing of the pharyngoesophageal segment in comparison to that in the preoperative pharyngogram. Complications include incomplete myotomy manifested as a persistent cricopharyngeal bar, fistula or abscess formation, and vocal cord paralysis because of recurrent laryngeal nerve damage.

Variations in Technique

Anterior Wall Lesions
Possible Perforation
Partial Gastrectomy
Gastric Outlet Obstruction
Esophageal Varices

There are different ways to perform an upper gastrointestinal (GI) barium study. In Chapter 2, a technique was described that relies primarily on barium filling and mucosal relief (i.e., single-contrast technique). The method described in this chapter relies primarily on double contrast, although it is actually a biphasic technique that combines the advantages of single and double contrast. Individual fluoroscopists generally develop their own routines and variations. Nevertheless, the techniques discussed in this chapter are representative of a reasonable approach for performing double-contrast upper GI examinations.^{1,2}

General Principles

Double-contrast upper GI studies are designed to coat the mucosal surface with a thin layer of high-density barium while the lumen is distended with gas. The routine examination should include the thoracic esophagus, stomach, and duodenum as far as the duodenojejunal junction. The examination should be performed quickly to maintain optimal mucosal coating and prevent barium filling of the duodenum and small bowel from obscuring the stomach. It is not critical that each segment of the upper GI tract be examined in anatomic sequence. For example, it may be preferable to examine the antrum, pylorus, and duodenum before significant overlap with the small bowel has occurred. Similarly, when the pharynx needs to be evaluated, it may be preferable to

perform this portion of the examination after the upper GI study has been completed. The technical and logistic details of the examination should also be tailored for individual studies based on the following: (1) the patient's presenting symptoms; (2) the anatomic configuration of the esophagus, stomach and duodenum; and (3) the specific abnormalities observed at fluoroscopy.

Components

BARIUM SUSPENSIONS

For the double-contrast examination, we use high-density 250% w/v barium (E-Z-HD; Bracco Diagnostics, Monroe Township, NJ). The preparation of the barium suspension is critical because slight deviations in concentration may impair the quality of mucosal coating and create artifacts.³

EFFERVESCENT AGENTS

Various effervescent agents are available in powder, granular, or liquid form.⁴ These agents release 300 to 400 mL of carbon dioxide on contact with fluid in the stomach.

HYPOTONIC AGENTS

The use of a hypotonic agent to relax the stomach and duodenum results in a better examination and allows the examiner additional time to achieve optimal mucosal coating. In the United States, the only suitable hypotonic agent is glucagon; an intravenous injection of 0.1 mg usually produces transient hypotonia of the stomach.⁵ In some patients, this hypotonic effect delays barium filling of the duodenum for several minutes, prolonging the examination. Anticholinergic agents may also be used to induce GI hypotonia,⁶ but these agents are contraindicated in patients with glaucoma, cardiac disease, and urinary retention.

RADIOGRAPHIC COMPONENTS

In modern radiology practice, fluoroscopic GI examinations are generally performed with digital fluoroscopy and spot imaging.⁷ The advantages of a digital system—better contrast resolution, shorter exposures, and faster examinations—more than compensate for a small decrease in spatial resolution. The study is reviewed at a computer workstation,⁸ with post-processing of the images for optimal interpretation.⁹ Afterward, the studies are archived on a central picture archiving and communications system (PACS), enabling easy electronic retrieval of prior studies for comparison with the current examinations.

Routine Technique

Selected views from a normal double-contrast upper GI study are shown in [Figure 17-1](#). We begin with a short review of the patient's history and symptoms. Special care is taken to ask whether the patient has had any previous surgery and whether the patient is taking any ulcerogenic medications. The examination usually starts with an intravenous injection of 0.1 mg of glucagon. After this injection, the patient ingests an

effervescent agent followed by 10 mL of water to facilitate the release of carbon dioxide in the stomach. The patient then stands in the left posterior oblique position and is asked to gulp the contents of a cup containing 120 mL of high-density barium as rapidly as possible while double-contrast views of the esophagus are obtained in rapid succession. These views should include the distal esophagus and gastroesophageal junction. Barium is often seen cascading into the gas-filled stomach (see [Fig. 17-1A](#)).

Figure 17-1 Representative images from a normal double-contrast upper GI study. **A.** Upright double-contrast view of the esophagus showing the distal esophagus with barium cascading (arrow) into the gas-filled stomach. **B.** Supine left posterior oblique view of the stomach showing normal areae gastricae in the gastric antrum and body and normal rugal folds along the greater curvature of the body. **C.** Right lateral view of the stomach with minimal filling of the duodenum. This view is particularly helpful for evaluating the cardia and retrogastric region. **D.** Semiupright right posterior oblique view of the high lesser curvature, upper body, and fundus. **E.** Supine left posterior oblique view of the duodenum showing the smooth, featureless appearance of the bulb. (**D** and **E** from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 17-2 Flow technique. With barium flowing across the dependent surface of the stomach, two polypoid lesions (arrows) are identified on the posterior wall. This AIDS patient had biopsy-proven Kaposi's sarcoma in the stomach.

After the esophagus has been examined, the table is lowered into the horizontal position, and the patient is turned a full circle to achieve adequate barium coating of all surfaces of the stomach. Supine, left posterior oblique, and right posterior oblique views of the gastric antrum and body are then obtained (see Fig. 17-1B). The patient is next placed in the recumbent right side down position for a double-contrast view of the gastric cardia and fundus (see Fig. 17-1C). The patient is then placed in the semiupright, right posterior oblique position for a view of the high lesser curvature, upper body, and fundus (see Fig. 17-1D) and then in the supine, left posterior oblique position for double-contrast views of the duodenal bulb and sweep (see Fig. 17-1E). Flow technique is subsequently performed by slowly rotating the patient from side to side to manipulate a thin pool of barium over the posterior (dependent) gastric wall. Flow technique is extremely valuable for demonstrating shallow protruded or depressed lesions on the dependent surface (Fig. 17-2).¹⁰

After the double-contrast phase of the study has been completed, the patient is placed in a prone, right anterior oblique position and asked to take discrete swallows of a thin, low-density barium suspension to evaluate esophageal motility (see Chapter 18). The patient then rapidly gulps thin barium for single-contrast views of the optimally distended thoracic esophagus. Prone and upright compression views of the barium-filled stomach and duodenum are then obtained. Finally, the fluoroscopist tests for spontaneous gastroesophageal reflux or reflux induced by a Valsalva maneuver to increase intra-abdominal pressure. If there is no evidence of gastroesophageal reflux with this maneuver, a water siphon test is performed to increase the sensitivity of the fluoroscopic examination for reflux.¹¹ Our routine double-contrast upper GI study is summarized in Table 17-1.

Anatomic Considerations

Although the normal anatomy of the upper GI tract is well known, several anatomic variations that are particularly well

TABLE 17-1 Routine Upper Gastrointestinal Technique: Double Contrast

Position	Purpose
Upright, LPO	Esophagus, double contrast
Supine, LPO	Stomach, antrum and body, double contrast
Supine	Stomach, antrum and body, double contrast
Supine, RPO	Stomach, antrum and body, double contrast
Right side down lateral	Stomach, cardia and fundus, double contrast
Supine, LPO	Antrum, pylorus, duodenal bulb and sweep, double contrast
Supine and supine obliques	Antrum and body, flow technique
Semiupright, RPO	Stomach, high lesser curvature and fundus, double contrast
Prone, RAO	Esophagus, function and barium filling
Prone or prone, RAO	Antrum and duodenum, compression
Upright	Antrum, lesser curvature, and duodenum, compression
Recumbent	Test for gastroesophageal reflux

LPO, left posterior oblique; RAO, right anterior oblique; RPO, right posterior oblique.

demonstrated by the double-contrast technique should be stressed.

ESOPHAGUS

The normal mucosal surface of the esophagus is smooth and featureless (Fig. 17-3A). When the esophagus is partially collapsed, the normal longitudinal folds are seen as smooth, straight structures no more than 1 to 3 mm in width (Fig. 17-3B). In some patients, fine transverse folds may also be observed in the esophagus because of transient contraction of the longitudinally oriented muscularis mucosae (Fig. 17-3C). These folds are almost always found to be associated with gastroesophageal reflux.¹² In contrast, focally spiculated transverse folds may be detected as a normal variant in the upper thoracic esophagus at the junction of the striated and smooth muscle near the level of the aortic arch (Fig. 17-3D); these are thought to result from localized weakening of the amplitude of peristalsis in this region.¹³ Finally, in older patients, small nodules may be visible on the mucosal surface of the esophagus because of glycogenic acanthosis, a common degenerative condition of no clinical significance (Fig. 17-4).¹⁴

The esophagus may be indented by normal extrinsic impressions from the aortic arch, left main bronchus, and heart (Fig. 17-5A). A smooth, gently sloping indentation may also be seen on the right posterolateral wall of the upper thoracic esophagus between the thoracic inlet and aortic arch in about 10% of patients (see Chapter 25).¹⁵ This indentation represents a normal anatomic variant resulting from an unusually prominent right inferior supra-azygous recess of the mediastinum abutting the esophagus. This variation should not be mistaken for adenopathy or other masses in the mediastinum impinging on the esophagus.¹⁵ In contrast, abnormal impressions may be caused by enlargement of normal structures such as the heart and aorta or by abnormal structures such as enlarged lymph nodes, mediastinal masses, or large vertebral osteophytes (Fig. 17-5B).

Figure 17-3 Normal esophagus. **A.** Double-contrast view. In the upright, left posterior oblique projection, the esophagus is thrown off the spine. Note the smooth, featureless appearance of the esophagus. **B.** Longitudinal folds. With the esophagus partially collapsed, the normal longitudinal folds are seen. **C.** Transverse folds. These transverse folds are thought to result from contraction of the longitudinally oriented muscularis mucosae and are almost always associated with gastroesophageal reflux. **D.** Spiculation of the upper thoracic esophagus caused by focally prominent, spiculated transverse folds. (**C** from Gohel VK, Edell SK, Laufer I, et al: *Transverse folds in the human esophagus*. *Radiology* 128:303–308, 1978.)

STOMACH

The surface of the stomach can be studied at several levels. The rugal folds are best seen when the stomach is incompletely distended and are most prominent along the greater curvature of the gastric body (Fig. 17-6A). Because rugal folds contain a submucosal core, any process (e.g., inflammatory cells or tumor) that infiltrates the submucosa may cause the folds to become thickened. Conversely, as the normal rugal folds are effaced with greater distention, a fine mucosal pattern, also known as the *areae gastricae*, can be visualized by

double-contrast technique (see Fig. 17-1B) and, occasionally, by single-contrast technique (see Fig. 17-6A).¹⁶ This reticulonodular mucosal pattern can become distorted by inflammatory or neoplastic lesions and also serves as a marker of the quality of mucosal coating. The *areae gastricae* are more likely to be visualized in older patients because of thinning of the mucous gel layer in the stomach with aging.¹⁷ Enlarged *areae gastricae* are sometimes observed in patients with increased acid secretion or chronic *Helicobacter pylori* gastritis.¹⁸ In other patients, fine transverse folds (also known as gastric striae) are seen in the gastric antrum as a sign of chronic antral gastritis

Figure 17-4 Glycogenic acanthosis. Small nodules (arrows) are seen on the mucosal surface of the midesophagus in an asymptomatic patient. These nodules result from a benign degenerative condition known as glycogenic acanthosis.

(Fig. 17-6B).¹⁹ In thin patients, the posterior wall of the stomach may be impressed by normal retrogastric structures (e.g., spleen and pancreas) that should not be mistaken for pathologic mass lesions (Fig. 17-6C). The gastric cardia may also be recognized on double-contrast views of the fundus by the presence of three or four stellate folds radiating to a central point at the gastroesophageal junction (also known as the cardiac rosette), sometimes associated with a hooding fold (Fig. 17-7).²⁰ In patients with ligamentous laxity and a small hiatal hernia, these anatomic landmarks may no longer be present. The cardiac rosette can also be distorted or obliterated by malignant tumors involving the cardia (see Chapters 26 and 32).

DUODENUM

The surface of the duodenal bulb is usually quite smooth. In some patients, double-contrast studies may reveal a fine feathery or velvety surface in the bulb, probably representing a normal villous pattern (Fig. 17-8A).²¹ In other patients, double-contrast studies may reveal small angular filling defects near the base of the duodenal bulb, a finding that is characteristic of heterotopic gastric mucosa (Fig. 17-8B).²² Still other patients may have a smooth round or ovoid mass with a central barium collection at the superior duodenal flexure (Fig. 17-8C). Although the appearance may resemble that of an ulcer with a surrounding mound of edema or even an ulcerated submucosal mass (i.e., a bull's-eye lesion), this finding actually results from

Figure 17-5 Extrinsic impressions on the esophagus. **A.** Normal impressions: 1, aortic arch; 2, left main bronchus; 3, heart; and 4, esophageal hiatus. **B.** Abnormal extrinsic impression on the posterior wall of the esophagus caused by a large thoracic osteophyte.

a normal anatomic variant in which there is an infolding of redundant mucosa at the superior duodenal flexure, also known as the duodenal pseudolesion or flexural fallacy.²³ Occasionally, the duodenal bulb contains tiny barium collections (Fig. 17-8D) representing normal pits in the duodenal mucosa that should not be mistaken for duodenal erosions.²⁴ However, these mucosal pits are not surrounded by radiolucent halos of edematous mucosa, whereas true erosions in the duodenum almost always have a varioliform appearance with surrounding mounds of edema. Finally, symmetric filling defects may be observed at the base of the duodenal bulb (abutting the medial and lateral margins of the pylorus) as a result of prolapsed antral mucosa, a finding of little or no clinical significance.

In the descending duodenum, the anatomy of the major papilla of Vater is particularly well demonstrated on double-contrast studies.²⁵ The major papilla is located on the medial wall of the descending duodenum and is usually associated with a longitudinal fold and a hooding fold (Fig. 17-9A). In contrast, the minor papilla is located on the anterior wall of the descending duodenum just proximal to the major papilla and is therefore best seen when the patient is in the prone position (Fig. 17-9B).

Variations in Technique

ANTERIOR WALL LESIONS

Routine double-contrast technique with the patient in a supine or supine oblique position is best for detecting protruded or depressed lesions on the posterior (dependent) wall of the

Figure 17-6 Normal surface patterns of the stomach. **A.** Prone compression views of the stomach with high-density barium show the rugal folds as branching, linear filling defects. Also note the fine reticular pattern of the areae gastricae. (See also [Fig. 17-1B](#).) **B.** Gastric striae in the distal antrum. Note the fine transverse folds traversing the distal antrum. **C.** Normal retrogastric impressions in a thin woman. The more superior extrinsic impression is caused by the spleen and the more inferior one is caused by the pancreas.

Figure 17-7 Normal cardia and its variations. **A.** Well-anchored cardia appears as a circular elevation with centrally radiating folds (the cardiac rosette). **B.** Stellate folds without the surrounding elevation caused by laxity of the ligamentous attachments. **C.** Further weakening of the ligaments with obliteration of the cardiac rosette. Note the crescentic line (arrow) crossing the area of the esophageal orifice. **D.** Severe ligamentous laxity with gastric folds converging superiorly (arrow) in a tiny hiatal hernia above the esophageal hiatus of the diaphragm. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

gastric antrum or body. In contrast, protruded or depressed lesions on the anterior wall may be seen as ring shadows etched in white on double-contrast views obtained with the patient in the supine position. Such lesions are usually visualized as filling defects (protruded lesions) or barium collections (depressed lesions) on compression views obtained with the patient in the prone position (Fig. 17-10). Double-contrast examination of the anterior wall of the stomach can also be performed with the patient in the prone position, turned slightly to the left, with the head of the table lowered.²⁶ Similarly, the anterior wall of the duodenum can be studied by double contrast with the patient in the prone position (see Fig. 17-9B).

POSSIBLE PERFORATION

When perforation of any portion of the GI tract is suspected because of underlying disease, surgery, or other iatrogenic causes, a water-soluble contrast agent such as diatrizoate meglumine and diatrizoate sodium (Gastroview; Mallinckrodt Pharmaceuticals, St. Louis) should be used.²⁷ If no extravasation of contrast material is demonstrated, the examination should be completed with high-density barium because the better definition achieved with this type of barium enables visualization of small leaks that cannot be detected with a water-soluble contrast agent.²⁸

PARTIAL GASTRECTOMY

After partial gastrectomy for ulcer disease or tumor, the double-contrast examination must be modified to compensate for the

absence of a pylorus (Fig. 17-11).²⁹ Important modifications include an increase in the dose of glucagon to at least 0.5 mg to delay emptying of barium from the remaining stomach and a smaller dose of an effervescent agent because there is less stomach to distend. In addition, the examination should not be started with the patient in the upright position because rapid emptying of barium in this position may prevent adequate visualization of the gastric remnant. Details of the examination are discussed in Chapter 35.

GASTRIC OUTLET OBSTRUCTION

When gastric outlet obstruction is suspected, the patient should initially be examined in the upright position to determine whether there is a fluid level in the stomach. If a fluid level is present, a single-contrast barium study should be performed to delineate the site and nature of the obstruction. In such cases, high-density barium should be used rather than thin barium, because high-density barium is more likely to traverse retained fluid or debris in the stomach and reach the site of obstruction.

ESOPHAGEAL VARICES

Esophageal varices are discussed in detail in Chapter 25. Esophageal varices are typically manifested by thickened, tortuous, or serpiginous longitudinal folds that are best demonstrated with the patient in the recumbent position, with coating of the esophageal mucosa by high-density barium or barium paste and the esophagus partially collapsed.³⁰

Figure 17-8 Normal surface patterns of the duodenum. **A.** A fine velvety pattern is seen in the duodenal bulb. **B.** Angular filling defects represent heterotopic gastric mucosa in the duodenal bulb. **C.** The flexural pseudolesion (arrow) results from infolding of a heaped-up area of redundant mucosa at the superior duodenal flexure. **D.** Multiple punctate collections of barium in the duodenal bulb represent normal mucosal pits.

Figure 17-9 Descending duodenum. **A.** The descending duodenum is seen through the gas-filled antrum with the patient in the left posterior oblique position. Note the major papilla (arrow) and its associated folds. **B.** Prone view shows the major papilla (short arrow) on the medial wall of the descending duodenum, with the minor papilla (long arrow) seen anteriorly above this level. (**B** from Laufer I, Levine MS [ed]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 17-10 Examination of the anterior wall of the stomach. The rugal folds on the anterior wall of the stomach are clearly seen with the patient in the prone position. The fundus is filled with gas. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 17-11 Postoperative stomach. **A.** Double-contrast view showing the normal postoperative appearance after a partial gastrectomy (Billroth II). **B.** Double-contrast view of the gastrojejunal anastomosis after a partial gastrectomy (Billroth II).

Motility Disorders of the Esophagus

DAVID J. OTT | MARC S. LEVINE

CHAPTER OUTLINE

Normal Esophageal Anatomy

Normal Esophageal Physiology

Radiographic Evaluation

Esophageal Motility Disorders

Primary Motility Disorders

Nonspecific Esophageal Motility Disorder

Secondary Motility Disorders

Motility disorders of the esophagus are an important cause of esophageal complaints, especially when symptoms are not readily explained by a structural abnormality. An understanding of esophageal anatomy and physiology is required for proper radiographic evaluation of normal and abnormal esophageal function. This chapter reviews the normal anatomy and physiology of the esophagus before discussing the radiographic evaluation of esophageal motility and the various esophageal motility disorders.

Normal Esophageal Anatomy

The esophagus is a muscular tube measuring 20 to 24 cm in length; it is composed of outer longitudinal and inner circular muscle fibers and is lined by stratified squamous epithelium.¹ Striated muscle predominates in the upper third of the esophagus, with smooth muscle in the lower two thirds. The transition from striated to smooth muscle varies but usually occurs at the level of the aortic arch.^{1,2} Although this transitional zone is not evident on barium esophagography, certain motility disorders (e.g., collagen vascular diseases) may selectively involve the striated or smooth muscle portions of the esophagus.

Opening and closing of the upper and lower ends of the esophagus are regulated by the upper esophageal sphincter (UES) and lower esophageal sphincter (LES), respectively. The UES is located at the pharyngoesophageal junction and is formed primarily by the cricopharyngeal muscle, the horizontal portion of the inferior pharyngeal constrictor. The LES is not a distinct muscular entity but is defined manometrically as a high-pressure zone measuring 2 to 4 cm in length in the esophagogastric region.^{1,3} This physiologic sphincter corresponds in location to the anatomic esophageal vestibule.^{3,4}

Normal Esophageal Physiology

In the resting state, the esophageal body is normally collapsed, and the UES and LES are closed to prevent retrograde flow of esophageal and gastric contents.^{1,5} The major function of the esophagus is the transport of solids and liquids from the oral

cavity to the stomach. The chief mechanism of bolus transport is esophageal peristalsis, which is assisted by gravity in the upright position. Radiographic evaluation of esophageal peristalsis is therefore usually performed with the patient recumbent to eliminate the effect of gravity.

Primary esophageal peristalsis is initiated by swallowing. A rapid wave of inhibition (not apparent radiographically) is followed by a slower wave of contraction, which traverses the entire esophagus (Fig. 18-1). Relaxation of the UES occurs within 0.2 to 0.3 second of the initiation of swallowing, and relaxation of the LES occurs several seconds later.^{1,5,6} The LES remains relaxed as the oncoming bolus approaches the distal esophagus, returning to its contracted state shortly after the bolus reaches the stomach. The primary peristaltic contraction wave propagates through the esophagus in 6 to 8 seconds.

Secondary peristalsis and nonperistaltic contractions (NPCs) are other types of esophageal functional activity.^{1,6-9} Secondary peristalsis is initiated by local esophageal stimulation or distention, but is otherwise similar to primary peristalsis, propagating aborally. In contrast, NPCs (also known as tertiary contractions) are not propagated aborally. They typically involve the smooth muscle segment of the esophagus, occurring spontaneously or during swallowing. NPCs may be single or multiple, simultaneous or repetitive, and feeble or strong. Severe NPCs may narrow or obliterate the esophageal lumen, producing a characteristic corkscrew appearance on barium studies (Fig. 18-2). NPCs are nonspecific and may be related to a variety of motility disorders involving the esophagus.

Individual variations in esophageal function are primarily related to aging. In young adults, most wet swallows initiate a complete peristaltic sequence, followed invariably by LES relaxation.¹⁰ NPCs are rare in this age group. However, older patients often exhibit incomplete peristaltic sequences during swallowing, with occasional LES dysfunction and a higher prevalence and severity of NPCs, a condition known as presbyesophagus.¹⁰⁻¹³ The amplitude of peristalsis, as recorded manometrically, also decreases with age. Thus, mild functional disturbances of the esophagus that are observed in older adults must be interpreted with caution and correlated with the clinical findings.

Radiographic Evaluation

Radiographic evaluation of esophageal motility includes an examination of the esophageal body and both sphincters.^{1,4,7-9,14} During swallowing, the UES relaxes and the pharyngoesophageal segment opens in response to bolus distention. Incomplete relaxation of the UES may be manifested on barium studies by a persistent indentation on the posterior aspect of the pharyngoesophageal junction resulting from the contracted cricopharyngeal muscle (see Chapter 15).^{8,14} This finding is often associated with other signs of pharyngeal dysmotility, such as aspiration or stasis of barium within the valleculae and piriform sinuses. Motion-recording techniques (using videotape or

Figure 18-1 Manometric representation of normal esophageal peristalsis. Measurements are taken from multiple recording sites in the esophagus, including the upper esophageal sphincter (UES) and the lower esophageal sphincter (LES). After a wet swallow (WS), UES relaxation is followed almost immediately by prolonged LES relaxation. The primary peristaltic contraction wave is seen as an aborally progressing pressure peak. (From Dodds WJ: *Esophagus-radiology*. In Margulis AR, Burhenne HJ [eds]: *Alimentary Tract Radiology*, vol 1, 4th ed. St. Louis, CV Mosby, 1989, p 430.)

a digital recording device) facilitate evaluation of the pharynx and UES.

The fluoroscopic examination can be used to evaluate esophageal motility, but motion-recording techniques facilitate assessment of the findings. The patient is placed in the prone right anterior oblique (RAO) position and instructed to take single swallows of barium. At least five barium swallows are required for adequate evaluation of esophageal peristalsis and LES relaxation.^{4,7-9,15} Single swallows must be observed because a second swallow taken before completion of a primary contraction wave inhibits the propagating wave, so it can erroneously be mistaken for a peristaltic abnormality. In contrast, rapid, repetitive swallowing does not assess primary esophageal peristalsis but distends the esophagus maximally for structural evaluation (Fig. 18-3).

As barium is propelled into the esophagus through the relaxed UES, a normal primary peristaltic sequence is seen as an aboral contraction wave that obliterates the esophageal lumen and progressively strips the barium bolus from the esophagus (Fig. 18-4). This lumen-obliterating wave imparts an inverted V configuration to the top of the barium column, corresponding to the peristaltic pressure peak observed at manometry. In younger individuals, the peristaltic contraction wave normally strips all of the swallowed barium from the esophagus. Occasionally, so-called proximal escape of barium occurs at the level of the aortic arch (Fig. 18-5). This age-related phenomenon is caused by a low-amplitude pressure trough at the transition zone between the striated and smooth muscle portions of the esophagus, which prevents closure of the esophageal lumen

Figure 18-2 Nonperistaltic contractions in the esophagus.

A. Barium study of an 89-year-old man with dysphagia but no chest pain. The esophagus has a corkscrew appearance because of simultaneous nonperistaltic contractions. A nonspecific esophageal motility disorder was diagnosed on manometric examination. **B.** Another older man without esophageal symptoms has less severe simultaneous nonperistaltic contractions. (From Ott DJ: *Radiologic evaluation of esophageal dysphagia*. *Curr Probl Diagn Radiol* 17:1-33, 1988.)

Figure 18-3 Manometric representation of normal esophageal peristalsis. Measurements are taken from multiple recording levels in the esophagus. Rapid swallows cause prolonged lower esophageal sphincter (LES) relaxation but do not generate a primary peristaltic sequence until the final swallow. AA, Aortic arch; S, swallow.

Figure 18-4 Normal primary peristalsis. **A.** Schematic representation of normal primary peristalsis with a lumen-obliterating contraction wave stripping all of the barium from the esophagus. **B.** Videotaped temporal tracings of a 5-mL barium bolus at 1-second intervals show normal primary peristalsis. The tapered tops of the barium column correspond to the peristaltic contraction wave seen during synchronous manometry. The numbers on the vertical axis represent the positions of the manometric catheter ports above the LES. AA, Aortic arch; EGJ, esophagogastric junction; PEJ, pharyngoesophageal junction. and allows retrograde flow of barium.^{2,6,16} In almost all cases, proximal escape can readily be differentiated from true esophageal motility disorders.

Esophageal Motility Disorders

Esophageal motility disorders may be classified as primary or secondary (Table 18-1).^{1,5,7-9,17-19} Primary motility disorders mainly involve the esophagus, whereas secondary esophageal motility disorders result from a wide variety of systemic diseases or from physical or chemical injury of the esophagus. Esophageal motility disorders may also be classified manometrically into four groups: (1) inadequate LES relaxation (classic achalasia); (2) uncoordinated contraction (diffuse esophageal spasm); (3) hypercontraction (nutcracker esophagus and hypertensive LES); and (4) hypocontraction (nonspecific esophageal motility disorders, presbyesophagus, and secondary esophageal motility disorders).¹⁷⁻¹⁹ Because this classification of esophageal motility disorders is based on manometric findings that cannot be adequately quantified on barium

Figure 18-5 Proximal escape. **A.** Manometric representation shows normal primary peristalsis with proximal escape because the contraction wave fails to obliterate the lumen completely at the level of the aortic arch (AA). Note that the peristaltic sequence continues aborally. **B.** Videotaped temporal tracings of a 5-mL barium bolus at 1-second intervals show normal primary peristalsis associated with proximal escape (arrow). The lower esophagus is normally stripped of barium below the area of escape. The numbers on the vertical axis represent the positions of the manometric catheter ports above the LES. EGJ, Esophagogastric junction; PEJ, pharyngoesophageal junction. (**A** from Ott DJ: *Radiologic evaluation of esophageal dysphagia*. *Curr Probl Diagn Radiol* 17:1–33, 1988; **B** from Ott DJ, Chen YM, Hewson EG, et al: *Esophageal motility: Assessment with synchronous videotape fluoroscopy and manometry*. *Radiology* 173:419–422, 1989.)

studies, we have instead chosen to classify primary and secondary esophageal motility disorders conceptually in this chapter (see Table 18-1).

PRIMARY MOTILITY DISORDERS

Achalasia

Achalasia is a well-recognized esophageal motility disorder characterized by a combination of absent peristalsis in the esophagus and impaired LES opening in response to deglutition.^{1,7-9,17-21} Two forms of achalasia have been described, primary and secondary. Primary achalasia (also known as idiopathic achalasia) is caused by degeneration and loss of myenteric ganglia in the wall of the esophagus. The cause is unknown but is postulated to be secondary to viral or autoimmune disease.² In contrast, secondary achalasia (also known as pseudoachalasia) is a less common form caused by

TABLE 18-1 Classification of Esophageal Motility Disorders**PRIMARY MOTILITY DISORDERS (NEWER CLINICAL CATEGORIES)**

Achalasia and variants (inadequate lower esophageal sphincter relaxation)
 Diffuse esophageal spasm (uncoordinated contraction)
 Nutcracker esophagus (hypercontraction)
 Nonspecific esophageal motility disorder (hypocontraction)
 Presbyesophagus (questionable entity—hypocontraction)
 Hypertensive lower esophageal sphincter (hypercontraction)

SECONDARY MOTILITY DISORDERS (MANY WITH HYPOCONTRACTION)

Collagen-vascular disease
 Chemical or physical agents
 Reflux esophagitis
 Caustic esophagitis
 Radiation therapy
 Infectious causes
 Diabetes mellitus
 Alcoholism
 Endocrine disease
 Neuromuscular disorders
 Cerebrovascular disease
 Demyelinating disorders
 Chorea-related disorders
 Myasthenia gravis
 Muscular dystrophies
 Other rare causes
 Idiopathic intestinal pseudo-obstruction

Figure 18-6 Manometric representation of normal peristalsis and achalasia. Measurements are taken from multiple recording levels in the esophagus. In this example of achalasia, peristalsis and lower esophageal sphincter (LES) relaxation are absent, and LES pressure is elevated. AA, Aortic arch; S, swallow.

extraesophageal conditions (usually malignant tumors) that induce an achalasia-like motility disorder by a variety of proposed mechanisms.^{3,4} Long-standing primary achalasia may also be a precursor of esophageal carcinoma. The association with carcinoma varies, but in one study the risk of carcinoma was 9 to 28 times greater than that in the general population.²² For the remainder of this chapter, the term *achalasia* is used to denote primary achalasia.

Achalasia occurs equally in both genders and usually affects patients during the middle decades of life.^{5,7,20,21} Most patients seek medical attention because of long-standing, slowly progressive dysphagia for solids and liquids, often associated with regurgitation of bland, undigested food and saliva.²³ Painful swallowing and chest pain are less common. Weight loss may occur in severe cases. Patients with chronic regurgitation may develop recurrent episodes of coughing, choking, and aspiration pneumonia. If dysphagia has a recent onset and is rapidly progressive in older patients with radiographic or manometric findings of achalasia, secondary achalasia caused by malignancy should be strongly suspected (see Chapter 24).^{7,20,23-25}

Achalasia is characterized manometrically by the absence of primary peristalsis, elevated or normal resting LES pressures, and incomplete or absent LES relaxation in response to deglutition (Fig. 18-6).^{5,7,9,20} However, the presence and degree of LES relaxation on manometry are unreliable because some patients with typical clinical and radiographic findings of achalasia are found to have complete manometric relaxation of the LES.²⁶ Other patients may have variants of achalasia, with atypical manometric findings. A debated variant, vigorous achalasia, is characterized by high-amplitude, simultaneous, and repetitive contractions.^{20,27,28} These patients may present with chest pain and have less esophageal dilation. Another controversial variant, early achalasia, is characterized by aperistalsis, with normal

Figure 18-7 Achalasia. **A.** There is a dilated esophagus with smooth, tapered narrowing just above the level of the gastroesophageal junction. Esophageal peristalsis was absent at fluoroscopy. **B.** Close-up view shows smooth, beaklike tapering of the distal esophagus because of LES dysfunction.

LES relaxation.²⁹ Patients with early achalasia also have less esophageal dilation and tend to be younger. Both these variants may represent transitional motility disorders evolving toward classic achalasia.³⁰⁻³²

Achalasia is characterized on barium esophagography by the absence of primary peristalsis on all swallows.^{1,5,7-9,20} The distal esophagus typically has a smooth, tapered, beaklike appearance at the level of the esophageal hiatus (Fig. 18-7) because of LES

Figure 18-8 Advanced achalasia. **A.** There is a markedly dilated esophagus with tapered distal narrowing caused by incomplete opening of the LES. Note retained food in the esophagus. **B.** A double contour of the right mediastinal border is seen in another patient with advanced achalasia. The outer border represents the dilated esophagus projecting beyond the shadows of the aorta and heart. A small amount of retained barium is present in the distal esophagus. Also note the absence of gas in the proximal stomach.

dysfunction and failure of the barium bolus to distend the tonically contracted sphincter. The degree of esophageal dilation is variable, and some patients with early achalasia have little or no esophageal dilation.²⁹ Others with vigorous achalasia have repetitive NPCs associated with typical findings of achalasia.²⁷ Over time, the esophagus becomes increasingly distended, and retained food, secretions, and barium in the dilated esophagus (Fig. 18-8A) may obscure underlying esophagitis or even developing esophageal carcinomas. In such cases, the fluoroscopist can use a water flush technique in which the patient swallows tap water at the end of the fluoroscopic examination to clear residual barium from the distal esophagus and facilitate the detection of tumor.³³ Advanced achalasia may be recognized on chest radiographs when marked esophageal dilation produces a double contour of the right mediastinal border, and little or no gas enters the stomach (Fig. 18-8B). Eventually, some patients with long-standing disease develop a massively dilated esophagus that has a tortuous distal configuration, also known as the sigmoid esophagus of end-stage achalasia (Fig. 18-9).

Achalasia must be differentiated from other causes of narrowing in the distal esophagus (Table 18-2). In particular, an underlying carcinoma of the esophagogastric region must be excluded (Fig. 18-10).^{7-9,20,23-25} Although most malignant tumors in this region are characterized radiographically by mucosal irregularity or mass effect (see Fig. 18-10B), carcinoma of the cardia and other malignant tumors causing secondary achalasia may be manifested on barium studies by smooth, tapered narrowing of the distal esophagus and aperistalsis, mimicking the findings of primary achalasia (see Fig. 18-10A and Chapter 24).²³ Peptic strictures are another common cause of distal esophageal narrowing, but such strictures are rarely associated

Figure 18-9 Long-standing achalasia with a sigmoid esophagus. There is a massively dilated esophagus with a tortuous distal configuration and tapered narrowing (arrow) above the gastroesophageal junction caused by incomplete opening of the LES. The sigmoid esophagus is a sign of end-stage achalasia.

Figure 18-10 Secondary achalasia or pseudoachalasia. **A.** Smooth narrowing of the esophagogastric junction simulates achalasia. This patient had a scirrhous carcinoma of the proximal stomach invading the distal esophagus. **B.** Fluoroscopy in another patient revealed esophageal dilation and aperistalsis. However, there is irregular tapering of the esophagogastric region caused by gastric carcinoma. (**A** from Ott DJ: Radiologic evaluation of esophageal dysphagia. *Curr Probl Diagn Radiol* 17:1–33, 1988.)

TABLE 18-2 Differential Diagnosis of Achalasia

Postvagotomy effect

with aperistalsis, and affected individuals almost always have accompanying hiatal hernias, an unusual finding in achalasia.³⁴ Scleroderma is another cause of marked esophageal dilation, but these patients typically have a patulous, gaping esophagogastric junction, enabling differentiation from achalasia. Occasionally, peptic strictures complicating scleroderma may produce an appearance simulating that of achalasia, but the correct diagnosis is usually suggested by the presence of an associated hiatal hernia.

Achalasia may be treated by botulinum toxin injection of the LES in older patients who are not candidates for more invasive therapy, but repeated injections are required because the relaxant effect of the botulinum toxin on the LES is relatively short term.³⁵ In contrast, younger patients with achalasia may have more effective long-term treatment of achalasia by pneumatic dilation or laparoscopic or surgical myotomy.^{36–38} Radiographic evaluation of the esophagus immediately after pneumatic dilation is helpful in detecting serious complications such as perforation,^{20,39–43} but is of little value for determining the long-term efficacy of the procedure because of edema and spasm of the distal esophagus in the early

Figure 18-11 Complications of a Heller myotomy. **A.** There is a wide-mouthed outpouching or sacculation (arrow) of the distal esophagus caused by focal weakening of the wall at the site of a Heller myotomy for achalasia. **B.** A stricture (arrows) is present in the distal esophagus after a Heller myotomy in another patient with achalasia. The stricture was confirmed by endoscopy.

postoperative period.⁴³ After a Heller myotomy, a wide-mouthed outpouching or sacculation is typically present in the distal esophagus as a result of focal weakening of the wall in the region of the myotomy (Fig. 18-11A).⁴⁴ Successful treatment of achalasia may paradoxically be complicated by the development of gastroesophageal reflux, reflux esophagitis, and peptic strictures (Fig. 18-11B). For this reason, a “loose” or incomplete fundoplication is often performed at the time of the myotomy to prevent these complications.^{20,45,46} Occasionally, patients with intractable dysphagia from end-stage achalasia may require an esophagogastricectomy.^{5,8,20}

Radionuclide studies and timed barium swallows may aid in the diagnosis and management of achalasia.^{20,47,48} Radionuclide transit studies are particularly helpful for quantifying esophageal retention before and after therapy.⁴⁷ Similarly, timed barium swallows are simple to perform and enable ready quantification of esophageal emptying of barium for objective assessment of the patient's response to various forms of therapy.⁴⁸

Diffuse Esophageal Spasm

Diffuse esophageal spasm (DES) is an uncommon motility disorder of unknown cause that is characterized by chest pain, often accompanied by dysphagia, and intermittently abnormal esophageal motility.^{5,7–9,17,18,49} DES typically involves the smooth muscle portion of the esophagus. Some patients have marked smooth muscle hypertrophy with thickening of the esophageal wall,⁵⁰ whereas others have little or no wall thickening.^{51,52} DES is not classically thought to involve the LES, but recent studies have shown that DES is often associated with LES dysfunction.⁴⁹ As a result, some investigators believe that achalasia, vigorous

achalasia, and DES represent a spectrum of related esophageal motility disorders and that vigorous achalasia may occur as a transitional phase between DES and achalasia.^{5,7,17,49}

Patients with DES typically present with chest pain, often accompanied by dysphagia.^{5,17,18,49,52} Radiation of pain to the shoulder or back may simulate angina and may even be relieved by nitroglycerin. The pain is often spontaneous and not related to swallowing and can worsen during emotional stress. Other patients with DES may have dysphagia for solids or liquids without chest pain. Food impaction is a dramatic but unusual feature of this motility disorder.

The major manometric criteria for DES are simultaneous contractions on more than 10% of wet swallows and intermittently normal primary peristalsis.^{5,7,17,18,52} Associated findings include repetitive or prolonged-duration contractions, high-amplitude contractions, and frequent spontaneous contractions (Fig. 18-12). Some patients with DES have normal LES function, but others have incomplete LES relaxation during swallowing.^{17,18,49}

The radiographic features of DES reflect the manometric findings.^{1,7-9,49,52} Primary peristalsis is present in the cervical esophagus but intermittently absent in the thoracic esophagus. NPCs affect the smooth muscle portion of the esophagus, intermittently disrupting primary peristalsis (Fig. 18-13A). These NPCs are often repetitive and simultaneous and, if severe, may compartmentalize the esophageal lumen, producing a classic corkscrew appearance (Fig. 18-13B).^{7,8,52} In one study, however, lumen-obliterating NPCs were detected on esophagography in less than 15% of all patients with DES.⁴⁹ Instead, most patients had NPCs of mild to moderate magnitude that did not obliterate the esophageal lumen.⁴⁹ It should therefore be recognized that the severity of NPCs varies in patients with DES, and that the absence of a corkscrew esophagus on barium studies in no way excludes this diagnosis. It has also been shown that most patients with DES have impaired LES opening on barium studies, with the tapered, beaklike distal esophageal narrowing

typically associated with achalasia (Fig. 18-14).⁴⁹ Some patients with DES may develop pulsion diverticula or even giant epiphrenic diverticula as a complication of their esophageal dysmotility (Fig. 18-15).⁵³

Muscular thickening of the esophagus is uncommon in DES, but a wall thickness of 2 cm or more is occasionally seen (normal wall thickness is less than 4 mm).⁵⁰⁻⁵² Thickening of the esophageal wall can sometimes be estimated along the right lateral border of the upper thoracic esophagus on barium studies when the wall closely apposes the pleural reflection line. Alternatively, wall thickness can be evaluated directly by computed tomography (CT) or endoscopic ultrasound.^{50,51} In patients with DES, CT may reveal smooth circumferential wall thickening, predominantly in the distal esophagus (Fig. 18-16).⁵⁴ However, esophageal wall thickening on CT is a nonspecific imaging finding that may result from a variety of causes, including esophagitis and benign and malignant tumors involving the esophagus.⁵⁴

When patients with DES have chest pain because of high-amplitude esophageal contractions, drugs such as calcium channel blockers, long-acting nitrates, and anticholinergics have been shown to decrease the amplitude of these contractions, sometimes ameliorating the patient's symptoms.⁴⁹ However, patients who present with dysphagia because of

Figure 18-12 Manometric representation of normal peristalsis and diffuse esophageal spasm. Measurements are taken from multiple recording levels in the esophagus. Normal peristalsis is present in the upper esophagus but is replaced by simultaneous, repetitive contractions below the aortic arch (AA). Normal lower esophageal sphincter (LES) relaxation is seen. S, Swallow.

Figure 18-13 Diffuse esophageal spasm. **A.** This patient has diffuse esophageal spasm with intermittent disruption of primary peristalsis associated with a focally obliterated nonperistaltic contraction. **B.** Another patient has the typical corkscrew appearance of diffuse esophageal spasm. Clinical and manometric correlation is required to confirm the diagnosis because this appearance is nonspecific, especially in older adults. (From Levine MS, Rubesin SE, Ott DJ: Update on esophageal radiology. *AJR* 155:933-941, 1990.)

Figure 18-14 Diffuse esophageal spasm with LES dysfunction. This patient has diffuse esophageal spasm with multiple nonperistaltic contractions. There also is tapered narrowing of the distal esophagus (arrow) caused by incomplete opening of the LES.

impaired LES opening may have marked relief of dysphagia from endoscopic balloon dilation or botulinum toxin injection of the LES.⁴⁹ In the absence of symptoms, patients with manometric or radiographic findings of DES require no treatment.

Nutcracker Esophagus

Nutcracker esophagus is an esophageal motility disorder seen in some patients with chest pain or dysphagia.^{5,7,17,18,55-57} Manometric examination shows normal peristalsis, with distal contractions of abnormally high amplitude and prolonged duration (Fig. 18-17). The term *high-amplitude peristaltic esophageal contractions* has also been used to describe this entity. Debate has arisen over whether nutcracker esophagus is a true motility disorder or part of the normal spectrum of esophageal function.^{5,17,18,55-62}

Nutcracker esophagus is a manometric diagnosis made in patients with appropriate symptoms. The radiographic examination is normal or reveals only nonspecific findings such as nonperistaltic contractions.^{63,64} Nutcracker esophagus therefore is not a radiologic diagnosis.

NONSPECIFIC ESOPHAGEAL MOTILITY DISORDER

Nonspecific esophageal motility disorder (NEMD) is a catchall category used for patients with motility disturbances that do

Figure 18-15 Giant epiphrenic diverticulum. A giant diverticulum (arrows), also known as an epiphrenic diverticulum, is seen arising from the right lateral aspect of the distal esophagus. This usually develops as a pulsion diverticulum secondary to long-standing esophageal dysmotility.

not fit clinical, manometric, or radiographic criteria for classic motility disorders such as achalasia and DES.^{5,17,18,65,66} Patients with NEMD sometimes have dysphagia or chest pain, but symptoms may be minimal or absent. Manometric abnormalities include intermittent absence of peristalsis on 20% or more of wet swallows, low-amplitude peristalsis, prolonged duration of peristalsis, repetitive or triple-peaked contractions, and incomplete LES relaxation (Fig. 18-18).^{17,18,65} Esophagography may reveal disruption of primary peristalsis and a variable number of NPCs, mimicking other esophageal motility disorders such as DES and presbyesophagus (Fig. 18-19).⁷⁻⁹ Barium studies may also be normal in patients with NEMD who have only minor manometric abnormalities.⁷⁻⁹

Presbyesophagus

Presbyesophagus has become a controversial entity.^{7-9,11-14,67,68} As originally described, the term *presbyesophagus* referred to a form of esophageal motor dysfunction associated with aging that rarely causes esophageal symptoms such as chest pain or dysphagia.^{67,68} The major manometric criteria include a decreased frequency of normal peristalsis, increased frequency of simultaneous contractions and, less commonly, incomplete LES relaxation. Barium studies in these patients may also reveal intermittently weakened or absent peristalsis with a variable number of NPCs. In early reports of presbyesophagus, however, affected individuals often had underlying neurologic disorders or diabetes, which might have accounted for their esophageal dysmotility. Later manometric studies in older patients have shown only minor changes in esophageal motility with

Figure 18-16 Diffuse esophageal spasm on CT. Axial contrast-enhanced CT images of the chest show moderate esophageal wall thickening (arrow) just below the carina (**A**) and even greater esophageal wall thickening (arrow) more distally (**B**). Barium esophagography revealed characteristic findings of diffuse esophageal spasm with multiple nonperistaltic contractions at fluoroscopy. Esophageal wall thickening is thought to result from progressive hypertrophy of the muscularis propria in these patients. (From Goldberg MF, Levine MS, Torigian DA: Diffuse esophageal spasm: CT findings in seven patients. *AJR* 191:758–763, 2008.)

aging.^{11–13} Furthermore, many of the manometric criteria for presbyesophagus are similar to those for NEMD, which may be the preferred radiologic term for this form of esophageal dysfunction. Whatever terminology is used, presbyesophagus is a clinically trivial condition that should be differentiated from DES and other motility disorders associated with chest pain or dysphagia.

Hypertensive Lower Esophageal Sphincter

Hypertensive LES was first described in patients with esophageal symptoms who had unusually high resting LES pressures.^{5,17,18,69} Almost all patients have chest pain, and many have dysphagia. The reported manometric criteria include a resting LES pressure greater than 40 mm Hg, with normal LES relaxation and esophageal peristalsis. Barium studies are usually normal in these patients.⁶⁹ Like nutcracker esophagus,

Figure 18-17 Manometric representation of nutcracker esophagus. This patient had a normal radiographic examination. There is normal peristalsis (P) manometrically, with high-amplitude contractions (>200 mm Hg, lower two leads). Accentuated baseline activity in the 13-cm lead is cardiac artifact. LES, Lower esophageal sphincter; WS, wet swallow. (Redrawn from Ott DJ, Richter JE, Chen YM, et al: Esophageal radiography and manometry: Correlation in 172 patients with dysphagia. *AJR* 149: 307–311, 1987.)

Figure 18-18 Manometric representation of nonspecific esophageal motility disorder. There is nontransmitted peristalsis (NT) in the lower leads and repetitive contractions during transmitted peristalsis (P). LES, Lower esophageal sphincter; WS, wet swallow. (Redrawn from Ott DJ, Richter JE, Chen YM, et al: Esophageal radiography and manometry: Correlation in 172 patients with dysphagia. *AJR* 149:307–311, 1987.)

hypertensive LES is thought to be a manometric diagnosis rather than a radiologic diagnosis.

SECONDARY MOTILITY DISORDERS

The causes of secondary esophageal motility disorders are numerous and varied (see Table 18-1).^{1,7–9,17–19,70} The radiographic findings are nonspecific and are often similar to those

Figure 18-19 Nonspecific esophageal motility disorder. **A.** This asymptomatic patient had simultaneous nonperistaltic contractions. Primary peristalsis was disrupted intermittently at fluoroscopy. Nonspecific esophageal motility disorder was diagnosed by manometry. **B.** Multiple nonperistaltic contractions and disrupted primary peristalsis are seen in another patient with nonspecific esophageal motility disorder. Clinical and manometric correlation are needed to distinguish this condition from diffuse esophageal spasm. (From Levine MS, Rubesin SE, Ott DJ: Update on esophageal radiology. *AJR* 155:933–941, 1990.)

described for NEMD. Thus, clinical correlation is critical for the proper diagnosis of secondary esophageal motility disorders.

Gastroesophageal Reflux Disease

Patients with gastroesophageal reflux disease (GERD) often have esophageal dysmotility that is characterized on barium studies and manometry by intermittently decreased or absent primary peristalsis in the mid and lower esophagus, without accompanying NPCs.^{71,72} This form of esophageal dysmotility should be differentiated from DES, NEMD, and presbyesophagus, which are almost always associated with NPCs of variable number and severity. It is uncertain whether the dysmotility of GERD is caused by refluxed acid in the esophagus, physical injury from reflux esophagitis, or a combination of both.⁷³ Whatever the pathogenesis, abnormal peristalsis in patients with GERD impairs the clearance of refluxed acid from the

Figure 18-20 Manometric representation of normal peristalsis and scleroderma. Measurements are taken from multiple recording levels in the esophagus. Normal peristalsis is present in the upper esophagus, with absence of peristalsis in the smooth muscle segment. The lower esophageal sphincter (LES) also shows low resting pressure. AA, Aortic arch; S, swallow.

esophagus, leading to a vicious cycle, with progressively severe reflux esophagitis.⁷⁴ The presence of esophageal dysmotility without NPCs on barium studies should therefore elicit a careful search for GERD and its sequelae. Rarely, reflux esophagitis may be manifested on barium studies by esophageal aperistalsis.⁷⁵ It has been postulated that this severe form of esophageal dysmotility is secondary to neuronal damage in Auerbach's plexus from reflux esophagitis.⁷⁵

Collagen Vascular Diseases

Collagen vascular diseases are characterized by immunologic and inflammatory changes in connective tissue, typically involving multiple organ systems. The esophagus is often involved by collagen vascular disease, most commonly scleroderma, mixed connective tissue disease, dermatomyositis, and polymyositis.^{17-19,76} Although scleroderma and mixed connective tissue disease typically involve the lower two thirds of the esophagus, which contains smooth muscle in its wall, dermatomyositis and polymyositis usually involve the pharynx and upper third of the esophagus, which contain striated muscle.

Scleroderma is characterized by fibrosis and degenerative changes in the skin, synovium, and parenchyma of multiple organs, including the esophagus. Esophageal involvement occurs in most patients with scleroderma, with the smooth muscle portion and LES predominantly affected.^{17-19,76,77} Because of resulting LES incompetence, symptoms of gastroesophageal reflux are common. Affected individuals may subsequently develop dysphagia secondary to abnormal motility, reflux esophagitis, or peptic strictures. Manometric features of scleroderma include decreased or absent resting LES pressure and markedly weakened or absent peristalsis in the lower two thirds of the esophagus (Fig. 18-20).^{17-19,76,77} Barium studies typically reveal absent peristalsis in the smooth muscle portion of the esophagus, with a markedly dilated esophagus, patulous gastroesophageal junction, and free gastroesophageal reflux, with poor clearance of refluxed barium from the esophagus

after reflux occurs (Fig. 18-21A). As a result, these patients often develop severe reflux esophagitis and peptic strictures (Fig. 18-21B). The major consideration in the differential diagnosis for a dilated, aperistaltic esophagus is achalasia, but this condition is almost always associated with tapered distal esophageal narrowing, enabling differentiation from scleroderma. Occasionally, patients with scleroderma may develop superimposed *Candida* esophagitis secondary to stasis and colonization of the esophagus by the fungal organism.⁷⁸

Other Secondary Motility Disorders

A variety of conditions may be associated with motility disorders in the esophagus. Of the infectious causes, Chagas' disease has the most specific appearance.^{5,17-19} This infection occurs primarily in South America and is caused by a protozoan organism, *Trypanosoma cruzi*. The disease affects multiple organs, including the myenteric plexus of the gastrointestinal tract, and may produce esophageal abnormalities identical to those in achalasia.

A variety of metabolic and endocrine disorders may affect esophageal motor function. In diabetic patients with peripheral neuropathy, manometric and radiographic abnormalities of the esophagus are common.^{5,17-19} The most frequent findings on barium studies include decreased primary peristalsis, NPCs, and mild esophageal dilation. Esophageal dysmotility is also common in alcoholic patients, but this dysmotility may be reversed by withdrawal of alcohol.⁷⁹

Esophageal motility may also be affected by a variety of neuromuscular disorders that predominantly involve the pharynx and upper esophagus. Finally, idiopathic intestinal pseudo-obstruction is a poorly understood syndrome that is sometimes associated with esophageal dysmotility, producing a radiographic appearance indistinguishable from that of achalasia.¹⁷⁻¹⁹

Figure 18-21 Esophageal involvement by scleroderma.

A. This patient has a dilated esophagus and a patulous esophagogastric junction. Esophageal peristalsis was absent at fluoroscopy. **B.** Another patient with scleroderma has developed a peptic stricture (open arrows) as a complication of reflux disease. Also note a small hiatal hernia (curved arrow) and sacculations (straight arrows) in the distal esophagus above the level of the stricture.

Gastroesophageal Reflux Disease

MARC S. LEVINE

CHAPTER OUTLINE

Reflux Esophagitis

Pathogenesis

Relationship Among Hiatal Hernia, Gastroesophageal Reflux, and Reflux Esophagitis

Clinical Findings

Diagnosis

Radiographic Findings

Differential Diagnosis

Barrett's Esophagus

Clinical Findings

Endoscopic and Histologic Findings

Radiographic Findings

Differential Diagnosis

Gastroesophageal reflux disease (GERD) is the most common inflammatory disease involving the esophagus, with a prevalence of 10% to 20% in the West.^{1,2} In the past, barium studies were advocated for patients with reflux symptoms primarily to show the presence of a hiatal hernia or gastroesophageal reflux (GER), detect complications such as deep ulcers or strictures, and rule out other organic or motor abnormalities in the esophagus that can mimic reflux disease. By permitting a more detailed assessment of the esophageal mucosa, however, double-contrast radiographic techniques have made it possible to detect superficial ulceration and other changes of mild or moderate esophagitis before the development of deep ulcers or strictures. Double-contrast esophagography is also a useful screening examination for Barrett's esophagus. With double-contrast techniques, barium studies therefore have a major role in the evaluation of patients with GERD.

Reflux Esophagitis

PATHOGENESIS

Reflux esophagitis is thought to be a multifactorial process related to the frequency and duration of reflux episodes, content of the refluxed material, and resistance of the esophageal mucosa.³⁻⁸ GER occurs when lower esophageal sphincter (LES) pressure is decreased or absent, so the major barrier to reflux is lost.^{3-5,9} In most patients, however, these reflux episodes result not from a sustained decrease in resting sphincter pressure but from multiple transient LES relaxations that frequently occur at night.^{6,10-12}

The severity of GERD depends not only on the frequency of reflux episodes but also on their duration. Because the duration of reflux is related to the efficacy of esophageal clearance by peristalsis, dysmotility exacerbates reflux disease and increases

the risk of developing esophagitis by prolonging exposure to refluxed acid.^{4,5} As a result, esophageal involvement by scleroderma often leads to severe esophagitis because of absent peristalsis and extremely poor clearance of peptic acid from the esophagus after reflux has occurred. In one study, 60% of patients with scleroderma who underwent endoscopy had evidence of reflux esophagitis.¹³

The severity of reflux disease also depends on the content of the refluxed material. Hydrochloric acid and pepsin are the noxious agents most responsible for injuring esophageal mucosa. These agents appear to have a synergistic effect, so reflux of acid and pepsin produces greater mucosal injury than reflux of acid alone.¹⁴ The concentration of refluxed acid is another important determinant of the degree of injury. Patients with Zollinger-Ellison syndrome are therefore more likely to develop severe esophagitis or strictures because of the high acidity of refluxed peptic juices into the esophagus.¹⁵⁻¹⁷

Finally, the severity of reflux esophagitis depends on the intrinsic resistance of the esophageal mucosa.^{4-6,8} Because mucosal resistance and esophageal motor function deteriorate with age, older patients are at greater risk for developing reflux esophagitis.

RELATIONSHIP AMONG HIATAL HERNIA, GASTROESOPHAGEAL REFLUX, AND REFLUX ESOPHAGITIS

Axial hiatal hernias occur more frequently in older patients because of progressive weakening of the ligaments that anchor the gastroesophageal junction to the surrounding esophageal hiatus of the diaphragm.^{4,18} There is considerable controversy about the relationship between a hiatal hernia and the subsequent development of GER or reflux esophagitis. Because most patients with clinically significant GERD have evidence of a hiatal hernia, it has been postulated that the presence of a hernia predisposes patients to the development of GER and reflux esophagitis.^{19,20} Nevertheless, many patients with a hiatal hernia have no evidence of GER, and many patients with GER have no evidence of a hernia.^{21,22} Thus, intrinsic LES dysfunction is probably the major factor in the development of GER, independent of the anatomic location of the sphincter above or below the diaphragm.^{3,5,21}

Although a hiatal hernia by itself is a poor predictor of GERD, most patients with severe reflux esophagitis or reflux-induced (peptic) strictures have hiatal hernias.^{5,23,24} There is evidence that marked acid reflux causes longitudinal esophageal shortening, disrupting the ligaments surrounding the gastroesophageal junction.²⁵ Thus, the hernia may represent an effect rather than a cause of esophagitis in these patients.

Similarly, GER is a poor predictor of reflux esophagitis because reflux may be demonstrated in some asymptomatic individuals but not in others with proven reflux esophagitis.^{4,5} Thus, the diagnosis of reflux esophagitis should be based not

on the presence or absence of a hiatal hernia or GER but on specific morphologic evidence of inflammatory changes in the esophagus.

CLINICAL FINDINGS

Patients with GERD classically present with heartburn—defined as retrosternal pain and burning that are worse after eating—and, less frequently, regurgitation.^{3,26,27} However, some patients may present with angina-like chest pain rather than heartburn. In one study, 43% of patients with chest pain of noncardiac origin were found to have GERD as the cause of their pain.²⁸ Others may present with epigastric pain or dyspepsia that is erroneously attributed to peptic ulcer disease.²⁹ Still others may have upper gastrointestinal (GI) bleeding, manifested by melena or guaiac-positive stool.³ However, major hemorrhage from reflux esophagitis is extremely uncommon.

An association between GERD and pulmonary problems has been well documented. Abnormal reflux has been reported in more than 80% of adult patients with asthma.³⁰ These patients typically present with nocturnal coughing or wheezing and do not have an allergic component to their asthma.²⁶ It has been postulated that this condition is caused by aspiration of refluxed acid into the airway or by vagally mediated bronchoconstriction secondary to reflux-induced irritation of the esophageal mucosa.³¹ Esophagopharyngeal reflux of peptic acid may also cause pharyngitis or laryngitis, manifested by a globus sensation, chronic cough, or hoarseness.^{26,32}

The perception of reflux symptoms depends on the degree and duration of exposure of the esophagus to refluxed acid.³³ Nevertheless, the severity of symptoms correlates poorly with the severity of reflux esophagitis on endoscopy.⁸ Some patients with marked reflux symptoms have normal endoscopic findings, whereas others with unequivocal endoscopic findings of esophagitis are asymptomatic. It has therefore been postulated that the development of reflux symptoms is sometimes related to an esophageal visceral hypersensitivity and inappropriately heightened perception because of underlying neuronal dysfunction rather than the actual degree of esophagitis in these patients.^{8,34}

The development of a peptic stricture is typically manifested by slowly progressive dysphagia for solids (followed by liquids) superimposed on a history of long-standing reflux symptoms.^{35,36} Nevertheless, 25% of patients with peptic strictures present with dysphagia as the initial manifestation of their disease.³⁶ Weight loss is usually minimal because patients with peptic strictures modify their diets to compensate for their dysphagia. Substantial weight loss should therefore raise concern about the possibility of a malignant esophageal stricture (see Chapter 23).

DIAGNOSIS

Patients with reflux symptoms may undergo various clinical tests to determine whether the symptoms are esophageal in origin and whether there are objective findings of GER or reflux esophagitis. GER may be assessed by radiologic, scintigraphic, manometric, or esophageal pH monitoring techniques. Esophagography or endoscopy is required to establish a diagnosis of reflux esophagitis. Barium studies are particularly useful for evaluating patients with GERD when surgical treatment is planned.³⁷

Gastroesophageal Reflux

Spontaneous GER is detected on barium studies in only 20% to 35% of patients with reflux esophagitis.^{5,24,38,39} Because GER often results from transient LES relaxations rather than from a sustained decrease in sphincter tone, intermittent episodes of reflux are easily missed during the brief period of fluoroscopic observation. Some radiologists advocate the use of the water siphon test (see Chapter 17), which increases the radiographic sensitivity for GER to 70%.³⁸ However, others do not favor the water siphon test, arguing that it is a physiologic technique with a low specificity for GER.^{22,40} Despite its limitations, I am a strong advocate of the water siphon test, which frequently permits detection of GER in patients in whom no reflux is observed spontaneously or with a Valsalva maneuver.

Gastroesophageal scintigraphy is an alternative technique for detecting and quantifying GER.^{41,42} Esophageal manometry can also be used to assess LES pressures, but many patients with normal resting sphincter pressures have intermittent GER secondary to transient LES relaxations.¹⁰⁻¹² Intraesophageal pH monitoring is thought to be the most accurate diagnostic test for GER,⁴³ but this test measures the acidity rather than the volume of refluxed material in the esophagus. Also, it has been shown that almost all patients with massive reflux on barium studies (defined as reflux of barium to or above the thoracic inlet with the patient in a recumbent position) have pathologic acid reflux on 24-hour esophageal pH monitoring.⁴⁴ Patients with massive GER on barium studies can therefore be further evaluated and treated for their reflux disease without need for pH monitoring.

Because the severity of GERD depends not only on the frequency of reflux episodes but also on their duration, esophageal clearance may be evaluated after reflux has occurred. Fluoroscopy, scintigraphy, intraesophageal pH monitoring, and manometry are tests used to evaluate esophageal clearance or motility.^{5,22,45,46}

Reflux Esophagitis

Conventional single-contrast esophagography has been considered to be an unreliable technique for detecting reflux esophagitis, with an overall sensitivity of only 50% to 75%.⁴⁷⁻⁵⁰ With the use of double-contrast technique, however, the radiographic sensitivity approaches 90%.^{48,50,51} A major advantage of double-contrast esophagography is that it permits a detailed assessment of the esophageal mucosa for superficial ulceration or other changes of mild or moderate esophagitis that cannot be detected with conventional barium studies. At the same time, single-contrast technique (with the patient in the prone position) is best for demonstrating areas of decreased distensibility in the distal esophagus caused by strictures or rings.⁵² A biphasic examination with upright double-contrast and prone single-contrast views of the esophagus therefore appears to be the best radiologic technique for evaluating patients with suspected reflux disease.

Endoscopy is generally advocated as the most definitive diagnostic test for reflux esophagitis. Various grading systems have been used to estimate the severity of esophagitis based on the endoscopic findings of erythema, friability, exudates, ulcers, and strictures.⁵³ Investigators have particularly focused on the importance of differentiating erosive esophagitis from nonerosive reflux disease.⁵⁴ Nevertheless, the use of endoscopy as the gold standard for reflux esophagitis is problematic because of

controversies about the endoscopic definition of esophagitis and interobserver reliability.⁵⁵⁻⁵⁷ In two studies, there was 50% or less agreement between the endoscopic and histologic findings of esophagitis.^{58,59} Thus, endoscopy is by no means an infallible technique for detecting this condition.

A definitive histologic diagnosis of reflux esophagitis can be made when endoscopic biopsy specimens reveal acute inflammatory changes with accumulation of neutrophils and eosinophils in the lamina propria. Basal cell hyperplasia of the squamous epithelium has also been recognized as an important sign of reflux disease, resulting from mucosal damage by refluxed acid and accelerated epithelial turnover in the esophagus.⁶⁰ Nevertheless, the histologic diagnosis of reflux esophagitis can be unreliable because of the patchy distribution of disease. In one study, 30% of patients with reflux symptoms had normal and abnormal biopsy specimens obtained from the same regions of the esophagus.⁶⁰ Some investigators have even questioned whether endoscopic biopsy specimens should be used as the gold standard for reflux esophagitis.⁶¹

RADIOGRAPHIC FINDINGS

Abnormal Motility

Between 25% and 50% of patients with reflux esophagitis have abnormal esophageal motility on manometry, manifested by weakening or disruption of primary peristalsis in the esophagus.^{4,62} In one study, esophagography revealed a distinct form of esophageal dysmotility in patients with GER in which there was intermittently weakened or absent peristalsis in the mid or lower esophagus without associated nonperistaltic contractions (NPCs).⁶³ In contrast, esophageal dysmotility associated with aging (also known as presbyesophagus) is characterized by a combination of weakened peristalsis and multiple repetitive NPCs of varying severity.⁶⁴ The presence of intermittently weakened or absent peristalsis without NPCs should therefore suggest underlying GERD on barium studies.⁶³

Much less frequently, esophageal aperistalsis may be the only radiographic finding in patients with reflux esophagitis.⁶⁵ In such cases, abnormal motility may be secondary to neuronal damage in Auerbach's plexus caused by the inflammatory process in the esophageal wall.⁶⁵ Conversely, preexisting esophageal dysmotility (e.g., that associated with scleroderma) may predispose patients to the development of reflux esophagitis by impairing clearance of refluxed acid from the esophagus. In either case, the combination of abnormal motility and GER results in a vicious cycle, sometimes leading to progressively severe esophagitis and stricture formation.⁵

Mucosal Nodularity

In the early stages of reflux esophagitis, mucosal edema and inflammation may be manifested on double-contrast images by a finely nodular or granular appearance in the distal third of the thoracic esophagus (Fig. 19-1).^{59,66-68} In one study, mucosal granularity was the most frequent and reliable sign of reflux esophagitis on double-contrast esophagograms, with a specificity and positive predictive value of about 90%.⁵⁹ This granularity is characterized by poorly defined lucencies that fade peripherally into the adjacent mucosa. Less frequently, reflux esophagitis may produce coarse nodularity of the mucosa. In almost all cases, this granularity or nodularity extends proximally from the gastroesophageal junction as a continuous area of disease.

Figure 19-1 Reflux esophagitis with a granular mucosa. There is a finely nodular or granular appearance of the mucosa extending proximally from the gastroesophageal junction as a continuous area of disease. (From Levine MS, Rubesin SE: *Diseases of the esophagus: Diagnosis with esophagography*. Radiology 237:414-427, 2005.)

More advanced reflux esophagitis may occasionally be associated with inflammatory exudates or pseudomembranes that resemble the plaquelike lesions of *Candida* esophagitis (Fig. 19-2),⁶⁹ but these patients usually present with reflux symptoms rather than odynophagia. A single large pseudomembrane can also be mistaken for a plaquelike carcinoma, particularly an adenocarcinoma arising in Barrett's mucosa.⁶⁹ However, pseudomembrane formation may be suggested by the presence of other satellite lesions or by changes in the size or shape of the lesions at fluoroscopy. When the radiographic findings are equivocal, endoscopy and biopsy should be performed for a definitive diagnosis.

Ulceration

Shallow ulcers and erosions associated with reflux esophagitis may appear on double-contrast barium studies as one or more tiny collections of barium in the distal esophagus at or near the gastroesophageal junction (Fig. 19-3).^{66,67} The ulcers can have a punctate, linear, stellate, or serpiginous configuration and are often associated with surrounding mounds of edematous mucosa, radiating folds, and puckering or saccululation of the adjacent esophageal wall (Fig. 19-4).^{66,67,70} Some patients may have diffuse ulceration of the distal third or even half of the thoracic esophagus. However, ulceration in reflux esophagitis tends to occur as a continuous area of disease extending proximally from the gastroesophageal junction, so the presence of

Figure 19-2 Reflux esophagitis with pseudomembranes. The pseudomembranes appear as discrete plaquelike defects indistinguishable from the plaques of candidiasis. (Courtesy Howard Kessler, MD, Philadelphia.)

one or more ulcers in the upper or middle thirds of the esophagus with sparing of the distal third should suggest another cause for the patient's disease.

Reflux esophagitis may also be manifested by a solitary ulcer in the distal esophagus at or near the gastroesophageal junction.⁷¹ These marginal ulcers may be recognized en face as discrete collections of barium (Fig. 19-5A) but are best visualized when the ulcers are viewed in profile (Fig. 19-5B). In one study, about 70% of these solitary reflux-induced ulcers were found to be located on the posterior wall of the esophagus (see Fig. 19-5B).⁷¹ Because GER often occurs during sleep, it has been postulated that patients who sleep primarily in the supine position are more likely to develop posterior wall ulcers as a result of prolonged exposure to refluxed acid that pools by gravity on the dependent (posterior) esophageal wall, causing maximal injury in this location.⁷¹

In advanced reflux esophagitis, the esophagus may have a grossly irregular contour with serrated or spiculated margins, wall thickening, and decreased distensibility secondary to extensive ulceration, edema, and spasm (Fig. 19-6).^{4,24,47,49} Occasionally, the narrowing and deformity associated with severe esophagitis can even mimic the appearance of an infiltrating carcinoma (Fig. 19-7). In such cases, endoscopy and biopsy are required for a definitive diagnosis.

Thickened Folds

In some patients with reflux esophagitis, submucosal edema and inflammation may lead to the development of thickened longitudinal folds (Fig. 19-8). Thickened folds are best seen on mucosal relief views of the collapsed or partially collapsed esophagus in which folds wider than 3 mm are thought to be abnormal.^{49,66} These thickened folds may have a smooth, nodular, scalloped, or crenulated appearance. Occasionally, they

Figure 19-3 Reflux esophagitis with superficial ulceration.

A. Multiple tiny ulcers (arrows) are seen en face in the distal esophagus near the gastroesophageal junction. Note radiating folds and puckering of the adjacent esophageal wall.
B. Another patient has punctate and linear ulcers in the distal esophagus.

Figure 19-4 Reflux esophagitis with a linear ulcer. Note the radiolucent halo of edematous mucosa and folds radiating toward the ulcer crater (arrow). (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 19-5 Reflux esophagitis with a discrete ulcer. This small ulcer (arrows) is seen both en face (**A**) and in profile (**B**) in the distal esophagus above a hiatal hernia. When viewed in profile (**B**), note how the ulcer is located on the right posterolateral wall of the distal esophagus. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 19-6 Advanced reflux esophagitis. There is decreased distensibility of the distal esophagus, which has an irregular, serrated contour because of extensive ulceration, edema, and spasm of the wall. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 19-7 Reflux esophagitis with a deep ulcer (straight arrow). There is also asymmetric narrowing of the distal esophagus with a relatively abrupt cutoff (curved arrow) at the proximal border of the narrowed segment. These findings were caused by edema and spasm, but the possibility of malignant tumor cannot be excluded on this image. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

may be tortuous or serpiginous, mimicking the appearance of esophageal varices.⁷²

Multiple delicate transverse folds may also be found in patients with GERD (Fig. 19-9).⁷³⁻⁷⁶ In the past, this appearance has been described as the feline esophagus because transverse esophageal folds are normally found in cats. These delicate transverse striations are only 1 to 2 mm wide and extend completely across the esophagus without interruption.⁷⁴ The folds occur as a transient phenomenon resulting from contraction of the longitudinally oriented muscularis mucosae,⁷⁵ so they may be seen on only one of a number of spot images obtained during the radiologic examination (see Fig. 19-9). It has been shown that almost 100% of patients with a feline esophagus have associated GER.⁷⁶ In fact, these transverse folds are most often observed at fluoroscopy during reflux of barium from the stomach rather than during swallowing of barium.⁷⁶ Occasionally, the transverse folds may be thickened in patients with reflux esophagitis (Fig. 19-10).⁶⁶

Inflammatory Esophagogastric Polyps

Other patients with reflux esophagitis may develop inflammatory esophagogastric polyps consisting of inflammatory and granulation tissue.⁷⁷⁻⁷⁹ The polyps usually appear on barium

studies as smooth, ovoid, or club-shaped protuberances in the lower esophagus atop a single prominent fold that tapers distally at the gastroesophageal junction (Fig. 19-11).^{77,78} Inflammatory esophagogastric polyps frequently straddle a hiatal hernia and may be associated with other radiographic findings of reflux esophagitis. Because these lesions have no malignant potential, endoscopy is not warranted when a typical inflammatory esophagogastric polyp is found on barium study (see Fig. 19-11A).^{78,79} If the lesions have a lobulated or irregular appearance (see Fig. 19-11B), however, endoscopy and biopsy should be performed to rule out malignant tumor.

Scarring and Strictures

Scarring from reflux esophagitis may be manifested by a variety of findings on esophagography. It is sometimes possible to detect slight flattening or puckering of the esophageal wall, radiating folds, or both in the absence of an actual stricture (Fig. 19-12). Asymmetric scarring from reflux esophagitis may also lead to focal outpouching or sacculation of the distal esophagus as a result of outward ballooning of the wall between areas of fibrosis (Fig. 19-13). Although these sacculations may resemble ulcer craters, they can usually be differentiated from ulcers by their more rounded appearance and changeable configuration

at fluoroscopy. Sacculations are particularly likely to develop in patients with scleroderma involving the esophagus, presumably because of the severe esophagitis that occurs in these individuals. Much less frequently, patients with esophageal involvement by scleroderma may develop wide-mouthed outpouchings or sacculations in the absence of strictures as a result of asymmetric smooth muscle atrophy and fibrosis (Fig. 19-14).⁸⁰

Scarring from reflux esophagitis may also be manifested by fixed transverse folds in the distal esophagus, producing a characteristic stepladder appearance as a result of pooling of barium between the folds (Fig. 19-15).⁷⁰ These transverse folds are usually 2 to 5 mm wide and do not extend more than halfway across the esophagus. They tend to be few in number and cannot be obliterated with esophageal distention. In most cases, there is other evidence of scarring from reflux esophagitis, and these transverse folds extend proximally a variable distance from the site of a distal stricture or scar.⁷⁰ The folds probably represent areas of heaped-up or crinkled mucosa caused by simultaneous longitudinal scarring from reflux esophagitis. These fixed transverse folds should be distinguished from the thin transverse striations that are sometimes observed as a transient finding in patients with a feline esophagus (see Fig. 19-9).⁷³⁻⁷⁶

Between 10% and 20% of patients with reflux esophagitis develop peptic strictures as a result of circumferential scarring of the distal esophagus.^{50,81} Accurate radiographic diagnosis of these strictures requires continuous drinking of low-density barium in the prone position to distend the distal esophagus and optimally demonstrate mild or even moderate strictures that are not visible on upright double-contrast images

Figure 19-8 Reflux esophagitis with thickened longitudinal folds. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 19-9 Transverse folds (feline esophagus) occurring as a transient phenomenon.

A. Fine transverse folds are seen in the distal esophagus.
B. Another image moments later shows obliteration of the folds. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 19-10 Reflux esophagitis with thickened transverse folds. There is also a peptic stricture (arrow) in the distal esophagus. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

(Fig. 19-16). With careful biphasic technique, barium studies have a sensitivity of almost 95% in detecting peptic strictures and may sometimes reveal strictures that are missed at endoscopy.^{82,83}

The vast majority of peptic strictures are located in the distal esophagus above an axial hiatal hernia (Fig. 19-17). Because many patients with GER or mild reflux esophagitis do not have a concomitant hernia, it has been postulated that scarring from reflux esophagitis leads not only to circumferential narrowing of the distal esophagus but also to longitudinal shortening and subsequent hernia formation.^{3,23,25} Whatever the explanation, a hiatal hernia is found on barium studies in more than 95% of patients with peptic strictures.²³ If the hernia fails to reduce below the diaphragm in the upright position and is a persistent finding at fluoroscopy, the patient is said to have developed a short esophagus. The latter finding has important implications for performing antireflux surgery because patients with a short esophagus may require an esophageal lengthening procedure such as a Collis gastroplasty at the time of Nissen fundoplication.⁸⁴ Conversely, when a hiatal hernia is not present in patients with distal esophageal strictures, the possibility of malignant tumor should be considered as a possible cause of these strictures because it is unlikely for a benign stricture to develop in the absence of a hernia.

The classic appearance of a smooth, tapered area of concentric narrowing in the distal esophagus above an axial hiatal hernia should be almost pathognomonic of a peptic stricture (see Fig. 19-17A).⁸⁵ Many peptic strictures have an asymmetric appearance, however, with puckering, deformity, or sacculation of one wall of the stricture caused by asymmetric scarring from reflux esophagitis (see Fig. 19-17B).⁸⁵ Other strictures may

Figure 19-11 Esophagogastric polyps. **A.** A prominent fold (straight arrows) is seen arising at the cardia and extending into the distal esophagus as a smooth polypoid protuberance (curved arrow). This appearance is characteristic of inflammatory polyps. **B.** An inflammatory esophagogastric polyp is seen in the distal esophagus in another patient. This lesion is more lobulated than most inflammatory polyps, so it cannot be differentiated from an adenomatous polyp or even an adenocarcinoma. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 19-12 Mild peptic scarring in the distal esophagus. **A.** There is slight flattening and puckering of the distal esophagus (arrow) with radiating folds in this region as a result of scarring from reflux esophagitis. **B.** In another patient, folds are seen radiating to a central scar (arrow).

Figure 19-13 Scarring from reflux esophagitis with sacculations. **A.** There are sacculations and radiating folds in the distal esophagus without evidence of a stricture. **B.** In another patient with greater scarring, there is a peptic stricture with several large sacculations seen en face (curved arrow) and in profile (straight arrows) in the distal esophagus. (**B** from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 19-14 Wide-mouthed sacculations in scleroderma. **A.** Two large sacculations are seen en face (black arrows) in the upper and midesophagus. Note how the upper sacculation extends superiorly just above the level of the aortic arch (white arrow). **B.** Additional view with the patient turned 90 degrees shows the sacculations in profile (arrows). (From Coggins CA, Levine MS, Kesack CD, et al: *Wide-mouthed sacculations in the esophagus: A radiographic finding in scleroderma*. AJR 176:953–954, 2001.)

involve a longer segment of the distal esophagus and may have irregular margins because of associated reflux esophagitis (see Fig. 19-17C).⁸²

Most peptic strictures range from 1 to 4 cm in length and from 0.2 to 2.0 cm in width.^{82,86} These strictures rarely cause esophageal obstruction, but some patients may develop intermittent food impactions above the proximal end of the stricture.³⁶ As many as 40% of radiographically diagnosed peptic strictures appear as ringlike areas of narrowing at the gastroesophageal junction with slightly tapered margins and a length of only 0.4 to 1 cm (Fig. 19-18).⁸⁶ Schatzki rings may produce similar radiographic findings, but they usually range from 2 to 4 mm in length and have more abrupt, symmetric margins (see Chapter 26).⁸⁷ Despite these subtle distinctions, there probably is overlap between ringlike peptic strictures and Schatzki rings detected on barium studies or endoscopy.

Distal esophageal webs have also been recognized as a manifestation of scarring from reflux esophagitis.⁸⁸ These webs are almost always associated with peptic strictures and tend to occur several centimeters above the gastroesophageal junction, so they can usually be differentiated from Schatzki rings by their more proximal location (Fig. 19-19). Some investigators have also found an association between cervical esophageal webs and GER,⁸⁹ possibly secondary to chronic injury from refluxed acid in the cervical esophagus.

Longer peptic strictures involving the distal third of the thoracic esophagus are relatively unusual. Such strictures may occur as a result of nasogastric intubation, protracted vomiting, bile reflux after partial or total gastrectomy, and

Zollinger-Ellison syndrome (see Chapter 21).^{15-17,35,90-92} Occasionally, patients with Zollinger-Ellison syndrome may present with long strictures in the distal esophagus as the initial manifestation of their disease (Fig. 19-20).^{15,16}

Esophageal intramural pseudodiverticula can sometimes be detected in the region of a peptic stricture (Fig. 19-21; see Chapter 21).⁹³ The pseudodiverticula probably occur as a sequela of chronic reflux esophagitis, but it is unclear why so few patients with esophagitis have this finding.

Many gastroenterologists believe that endoscopy and biopsy are required to rule out malignant tumor in all patients with radiographically diagnosed peptic strictures because of difficulty differentiating benign peptic strictures from infiltrating esophageal carcinomas on esophagography.⁹⁴⁻⁹⁶ In a large retrospective study, however, no patients with unequivocally benign-appearing peptic strictures in the distal esophagus on double-contrast esophagograms were found to have malignant tumor on endoscopy,⁸⁶ so endoscopy is not required to rule out esophageal cancer in these patients. If, however, the strictures have irregular contours, more abrupt margins, or other suspicious radiographic features, endoscopy and biopsy should be performed to rule out malignant tumor, particularly an adenocarcinoma arising in Barrett's esophagus (see Chapter 23).

DIFFERENTIAL DIAGNOSIS

Artifacts

Various technical artifacts may simulate the appearance of small ulcers on double-contrast esophagography.^{66,97} When barium

Figure 19-15 Fixed transverse folds in the esophagus.

Multiple transverse folds in the distal esophagus produce a stepladder appearance caused by longitudinal scarring from reflux esophagitis. (From Levine MS, Goldstein HM: *Fixed transverse folds in the esophagus: A sign of reflux esophagitis*. *AJR* 143:275–278, 1984.)

agents are improperly prepared, barium precipitates can be mistaken for numerous tiny ulcers (Fig. 19-22A). A similar appearance may also result from transient mucosal crinkling because of incomplete esophageal distention. Occasionally, an irregular Z line at the squamocolumnar junction may resemble a focal area of superficial ulceration. Even prominent interstitial lung markings seen through the esophagus may create the erroneous impression of ulceration.

Apparent mucosal granularity or nodularity may be caused by undissolved effervescent agent, gas bubbles, or debris in the esophagus (Fig. 19-22B). As a result, the increased sensitivity of the double-contrast study has been compromised by the increased number of false-positive examinations with this technique.^{48,50} If an artifact is suspected, however, additional double-contrast images should be obtained to demonstrate the transient nature of these findings.

Mucosal Nodularity

Glycogenic acanthosis should be the major consideration in the differential diagnosis of a nodular esophageal mucosa. This benign, degenerative condition is manifested on esophagography by multiple small, rounded nodules or plaques in the esophagus that can resemble the nodular mucosa of reflux esophagitis (see Chapter 22).^{98,99} The nodules of glycogenic acanthosis tend to be more well defined than those of reflux esophagitis, however, and are usually more prominent in the midesophagus than in the distal esophagus. The clinical history

Figure 19-16 Peptic stricture seen only on prone single-contrast views of the esophagus.

A. Double-contrast view with the patient upright shows no evidence of narrowing in the distal esophagus. **B.** Single-contrast view from the same examination with the patient prone reveals an unequivocal peptic stricture (arrow) above a hiatal hernia. Even in retrospect, this short stricture was not visible on double-contrast views because of inadequate distention of this region.

is also helpful because patients with glycogenic acanthosis are almost always asymptomatic.⁹⁸

Candida esophagitis may occasionally produce a finely nodular or granular appearance in the esophagus, mimicking the appearance of reflux esophagitis (see Chapter 20). This form of *Candida* esophagitis has been observed more frequently in patients with AIDS.¹⁰⁰ Opportunistic esophagitis should be suggested by the typical history of odynophagia in an immunocompromised patient.

Rarely, superficial spreading carcinoma may produce a reticulonodular appearance of the mucosa, but the area of involvement is usually more localized than that in reflux esophagitis, and the distal esophagus is often spared.¹⁰¹ Finally, leukoplakia, squamous papillomatosis, and acanthosis nigricans are rare causes of mucosal nodularity in the esophagus; the diagnosis is usually made unexpectedly at endoscopy or autopsy in these patients (see Chapter 22).

Ulceration

Although reflux esophagitis is the most common cause of superficial ulceration in the esophagus, shallow ulcers and erosions may be caused by other types of esophagitis, including herpes esophagitis and drug-induced esophagitis.^{102,103} Unlike

Figure 19-17 Peptic strictures. **A.** There is a concentric area of smooth, tapered narrowing in the distal esophagus above a hiatal hernia. This is the classic appearance of a peptic stricture. **B.** In another patient, there is an eccentric stricture with asymmetric narrowing and deformity of the distal esophagus. **C.** This peptic stricture involves a longer segment of the distal esophagus and has a more irregular contour. (**A** from Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989; **B** from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

reflux esophagitis, herpes esophagitis and drug-induced esophagitis tend to involve the upper or midesophagus with distal esophageal sparing (see Chapters 20 and 21), and are not usually associated with a hiatal hernia or GER. The correct diagnosis should also be suggested by a clinical history of odynophagia in immunocompromised patients or in those taking oral medications such as tetracycline.

Esophageal involvement by Crohn's disease may occasionally be manifested by tiny aphthoid ulcers, mimicking the findings of reflux esophagitis.¹⁰⁴ Esophageal Crohn's disease is uncommon, however, and these patients almost always have concomitant Crohn's disease in the small bowel or colon. More extensive ulceration may be caused by opportunistic infection, caustic ingestion, and mediastinal irradiation, but the correct diagnosis is usually suggested by the clinical history and presentation (see Chapters 20 and 21).

Thickened Folds

Thickened longitudinal folds in the esophagus may be caused by esophageal varices or by any inflammatory or neoplastic process that involves the submucosa. Although varices may occasionally resemble the thickened folds of esophagitis, they

tend to be more tortuous or serpiginous and can usually be effaced to a greater degree or even obliterated by esophageal distention. Rarely, varicoid carcinomas can also be mistaken for esophagitis on a single image.¹⁰⁵ Because the folds are infiltrated by tumor, however, they are unaffected by esophageal peristalsis and cannot be substantially effaced by esophageal distention. As a result, these entities can usually be differentiated at fluoroscopy.

Scarring and Strictures

Fixed transverse folds in the esophagus secondary to scarring from reflux esophagitis should be distinguished not only from the delicate transverse striations of the feline esophagus but also from the broad transverse bands associated with NPCs. The horizontal collections of barium pooled between these fixed transverse folds also should not be mistaken for linear ulcers. The regularity and symmetry of these folds should suggest the correct diagnosis.

A smooth, tapered area of concentric narrowing above a hiatal hernia poses little diagnostic dilemma, but not all peptic strictures have this classic appearance. If suspicious radiographic features such as asymmetry, abrupt margins, and

Figure 19-18 Ringlike peptic stricture. There is a ringlike stricture (arrows) in the distal esophagus above a hiatal hernia. Although this stricture could be mistaken for a Schatzki ring, it has a longer vertical height and more tapered margins than a true Schatzki ring. (From Luedtke P, Levine MS, Rubesin SE, et al: *Radiologic diagnosis of benign esophageal strictures: A pattern approach*. RadioGraphics 23:897–909, 2003.)

mucosal nodularity or ulceration are identified on the barium study, endoscopy and biopsy may be required to rule out an infiltrating carcinoma (Fig. 19-23).

Barrett's Esophagus

Barrett's esophagus is an acquired condition in which there is progressive columnar metaplasia of the distal esophagus secondary to long-standing GER and reflux esophagitis.¹⁰⁶⁻¹¹⁰ The diagnosis of Barrett's esophagus was traditionally reserved for patients who had endoscopic evidence of a columnar epithelium-lined esophagus extending more than 3 cm above the gastroesophageal junction and histopathologic findings of intestinal metaplasia on biopsy specimens.¹⁰⁸ In various studies, the prevalence of Barrett's esophagus in patients with reflux esophagitis has ranged from 5% to 15%, with an overall prevalence of about 10%.¹¹¹⁻¹¹⁵ These figures may underestimate the true prevalence of Barrett's esophagus in the general population. In one study, the number of cases of Barrett's esophagus at autopsy was 20 times greater than the number of cases at endoscopy.¹¹⁶ The findings in this study suggest that most cases

Figure 19-19 Peptic stricture with an associated web. The web (arrow) is located a greater distance from the gastroesophageal junction than expected for lower esophageal rings. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

of Barrett's esophagus remain undiagnosed because of the absence of esophageal symptoms. Nevertheless, Barrett's esophagus is being diagnosed with greater frequency as the number of patients who undergo endoscopy increases.

Despite its frequency, Barrett's esophagus would not be important if it were a benign entity. There is considerable evidence, however, that it is a premalignant condition associated with an increased risk of developing esophageal adenocarcinoma. These tumors evolve through a sequence of progressively severe epithelial dysplasia, eventually leading to the development of invasive carcinoma. In various studies, the prevalence of adenocarcinoma in patients with Barrett's esophagus has ranged from 2% to 46%, with an overall prevalence of about 10%.^{113,117,118} It should be recognized that prevalence data tend to exaggerate the risk of cancer by failing to identify all patients with underlying Barrett's esophagus. This problem is exacerbated by the fact that as many as 40% of patients with Barrett's esophagus remain asymptomatic until the development of a superimposed adenocarcinoma.¹¹⁹ In contrast, incidence data have shown that esophageal adenocarcinoma develops in only 0.1% to 0.5% of patients with Barrett's esophagus each year.^{120,121}

Whatever the precise cancer risk, the American College of Gastroenterology has recommended that patients with Barrett's esophagus undergo endoscopic surveillance at 2- to 3-year intervals to detect dysplastic changes before the development

Figure 19-20 Long peptic stricture caused by Zollinger-Ellison syndrome. There is a long area of narrowing in the distal esophagus with extensive ulceration in the region of the stricture. The unusual length of the strictures in these patients is presumably related to the higher acidity of refluxed peptic acid in Zollinger-Ellison syndrome. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

of overt cancer (see Chapter 23).¹²² The cost-effectiveness of endoscopic surveillance of patients with known Barrett's esophagus is supported by a Markov model showing that it compares favorably with other widely accepted screening strategies for cancer.¹²³ On the other hand, endoscopic surveillance of patients with Barrett's esophagus has not yet been shown to improve the mortality from esophageal adenocarcinoma. Thus, many questions remain about the role of endoscopic surveillance and its ultimate value in patients with Barrett's esophagus.

As our understanding of Barrett's esophagus has evolved, investigators have developed revised histopathologic criteria for this condition in which patients are classified as having long-segment (extending more than 3 cm from the gastroesophageal junction) or short-segment (extending 3 cm or less from the gastroesophageal junction) Barrett's esophagus based on the vertical extent of columnar metaplasia in the esophagus.¹²⁴ Short-segment Barrett's esophagus is even more common than long-segment Barrett's esophagus, with a reported prevalence of 10% to 15% at endoscopy.¹²⁵ Patients with short-segment Barrett's esophagus are more likely to develop dysplasia than the general population, but less likely to develop dysplasia than those with long-segment Barrett's esophagus.^{126,127} Although the cancer risk in these patients remains uncertain, some investigators believe that endoscopic surveillance is also warranted for patients with short-segment disease.¹²⁶⁻¹²⁹

Figure 19-21 Peptic strictures with esophageal intramural pseudodiverticulosis. **A.** There is a mild peptic stricture in the distal esophagus with multiple intramural pseudodiverticula seen en face and in profile (arrows) in the region of the stricture. **B.** This patient has a more severe peptic stricture with several pseudodiverticula (arrows) adjacent to the stricture. Note how the pseudodiverticula seem to be floating outside the wall of the esophagus without apparent communication with the lumen. The latter feature is characteristic of these structures. (A from Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

CLINICAL FINDINGS

The prevalence of Barrett's esophagus increases with age; the mean age is 55 to 60 years at the time of diagnosis.¹³⁰ This condition is more common in men than in women (2:1) and in whites than in blacks.¹³¹ Affected individuals may present with reflux symptoms because of their underlying reflux disease or with dysphagia because of the development of strictures. However, as many as 40% of patients with Barrett's esophagus are asymptomatic.¹²⁰ Such patients may not seek medical attention until the development of a superimposed esophageal adenocarcinoma (see Chapter 23). When patients with Barrett's esophagus do have reflux symptoms, they are usually treated with proton pump inhibitors or, if necessary, a laparoscopic fundoplication. It should be recognized, however, that medical or even surgical treatment of the underlying reflux disease does not cause this Barrett's epithelium to regress, so these individuals remain at risk for the development of esophageal adenocarcinoma even after a surgical fundoplication.¹³²

Figure 19-22 Double-contrast artifacts. **A.** Barium precipitates are present in the esophagus. These punctate collections of barium could be mistaken for tiny ulcers. **B.** In another patient, undissolved effervescent agent and gas bubbles in the esophagus cause apparent nodularity of the mucosa. If an artifact is suspected, additional double-contrast views should be obtained to demonstrate the transient nature of these findings. (**B** from Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

ENDOSCOPIC AND HISTOLOGIC FINDINGS

Long-segment Barrett's esophagus can be recognized at endoscopy by the presence of velvety, pinkish red columnar mucosa (often seen as islands or tongues) extending more than 3 cm above the LES or an endoscopically identified hiatal hernia.¹⁰⁸ Endoscopy is reported to have a sensitivity greater than 90% in diagnosing Barrett's esophagus based solely on the endoscopic findings.¹³³ Conversely, short-segment Barrett's esophagus is defined as endoscopically visualized columnar epithelium in the distal esophagus extending 3 cm or less above the gastroesophageal junction.¹²⁴

In the past, the histopathologic criteria for Barrett's esophagus included the presence of columnar epithelium (including a junctional-type epithelium, gastric fundic-type epithelium, and specialized columnar epithelium or incomplete form of intestinal metaplasia) on endoscopic biopsy specimens more than 3 cm above the gastroesophageal junction.¹³⁴ Subsequently, however, investigators focused on the importance of intestinal metaplasia on endoscopic biopsy specimens anywhere from the esophagus as the major prerequisite for a histologic diagnosis of Barrett's esophagus.^{124,135} This intestinal metaplasia is

Figure 19-23 Esophageal carcinoma. There is a relatively long area of narrowing in the distal esophagus that could be mistaken for a benign peptic stricture. However, the asymmetric contour and relatively abrupt proximal margins of the narrowed segment should suggest the possibility of malignant tumor. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

characterized histologically by goblet cells with acidic mucin and, in some cases, enterocyte differentiation with brush border formation. The revised definition for Barrett's esophagus was based on an emerging consensus that intestinal metaplasia represents the major type of epithelium predisposing these individuals to esophageal adenocarcinoma.¹³⁵

RADIOGRAPHIC FINDINGS

Long-Segment Barrett's Esophagus

The classic radiologic features of long-segment Barrett's esophagus consist of a midesophageal stricture or ulcer, often associated with an axial hiatal hernia or GER.¹³⁶⁻¹³⁸ The unusually high location of these strictures or ulcers can be attributed to the fact that they often occur in the proximal zone of columnar metaplasia at or near the elevated squamocolumnar junction. The strictures may appear on barium studies as ringlike constrictions (Fig. 19-24A) or, less commonly, as tapered areas of narrowing (Fig. 19-24B) in the midesophagus.¹³⁶ Occasionally, early strictures may be recognized on double-contrast studies as subtle contour abnormalities with focal indentations or gently sloping concavities of one wall.¹³⁹ Barrett's ulcers typically appear as relatively deep ulcer craters within the columnar mucosa, occurring at a considerable distance from

Figure 19-24 Barrett's esophagus with midesophageal strictures.

A. There is a ringlike constriction (arrow) in the midesophagus.

B. A smooth, tapered area of narrowing (arrow) is seen in the midesophagus. In the presence of a hiatal hernia and gastroesophageal reflux, a midesophageal stricture should be strongly suggestive of Barrett's esophagus. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 19-25 Barrett's esophagus with a high ulcer. There is a relatively deep ulcer crater (arrow) at a greater distance from the gastroesophageal junction than expected for uncomplicated reflux esophagitis. In the presence of a hiatal hernia and gastroesophageal reflux, a high ulcer should be strongly suggestive of Barrett's esophagus. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

the gastroesophageal junction (Fig. 19-25).¹⁴⁰ Because these findings are unusual in uncomplicated reflux disease, the presence of a midesophageal stricture or ulcer, particularly if associated with a hiatal hernia or GER, should be highly suggestive of Barrett's esophagus. However, studies have found that strictures are actually more common in the distal esophagus and that most cases do not fit the classic stereotype of a midesophageal stricture or ulcer.¹⁴¹⁻¹⁴⁴ Thus, esophagography is an inadequate screening examination for long-segment Barrett's esophagus when the diagnosis is made only in patients who have the classic radiologic features of this condition.

A reticular mucosal pattern has also been described as a relatively specific sign of long-segment Barrett's esophagus, particularly if located adjacent to a stricture.¹⁴² This delicate reticular pattern is characterized radiographically by innumerable tiny, barium-filled grooves or crevices on the esophageal mucosa, resembling the *areae gastricae* pattern found on double-contrast studies of the stomach (Fig. 19-26). In most cases, there is an adjacent stricture in the midesophagus or, less commonly, distal esophagus, with the reticular pattern seen extending distally a short but variable distance from the stricture.¹⁴² Occasionally, however, a reticular pattern of the mucosa may be observed as the only morphologic abnormality in

Barrett's esophagus without evidence of strictures.¹⁴⁵ Whether or not a stricture is present, a reticular pattern should be highly suggestive of Barrett's esophagus, and endoscopy and biopsy should be performed for a definitive diagnosis. Nevertheless, this finding has been observed in only 5% to 30% of patients with Barrett's esophagus,^{138,142-144,146} and its specificity has also been questioned.¹⁴⁷ Thus, most cases of long-segment Barrett's esophagus are missed on double-contrast esophagography if a reticular mucosal pattern is used as the primary radiologic criterion for diagnosing this condition.

Other common findings of reflux disease, such as hiatal hernias, GER, reflux esophagitis, and peptic strictures, can be detected on double-contrast esophagograms in more than 95% of patients with long-segment Barrett's esophagus (Fig. 19-27),^{137,138,141-144,146,148} but these findings frequently occur in patients with uncomplicated reflux disease in the absence of Barrett's esophagus. Thus, radiographic findings that are specific for Barrett's esophagus are not sensitive, and findings that are more sensitive are not specific. As a result, many investigators have traditionally believed that esophagography has limited value as a screening examination for Barrett's esophagus and that endoscopy and biopsy are required to diagnose this condition.

In 1988, Gilchrist and colleagues¹⁴⁹ introduced a novel approach for the diagnosis of long-segment Barrett's esophagus

Figure 19-26 Barrett's esophagus with a reticular mucosal pattern. **A.** There is an early stricture (black arrow) in the midesophagus with a reticular pattern extending distally a considerable distance from the stricture (approximately to the level of the white arrow). **B.** A close-up view better delineates this delicate reticular pattern. (From Levine MS, Kressel HY, Caroline DF, et al: Barrett esophagus: Reticular pattern of the mucosa. *Radiology* 147:663–667, 1983.)

on double-contrast esophagography by stratifying patients with reflux symptoms based on the following radiologic criteria: patients were classified at high risk if the images revealed the classic findings of a midesophageal stricture or ulcer or a reticular mucosal pattern; at moderate risk if the images revealed reflux esophagitis or a distal peptic stricture (previous studies have found that 10% of patients with reflux esophagitis and as many as 40% with peptic strictures have Barrett's esophagus^{111–115,150}); and at low risk if the images revealed a normal-appearing esophagus. The vast majority of patients classified at high risk and approximately 15% classified at moderate risk for Barrett's esophagus on double-contrast esophagograms were found to have this condition. Conversely, fewer than 1% of patients classified at low risk for Barrett's esophagus because of the absence of esophagitis or strictures were found to have this condition. Thus, esophagitis or peptic scarring severe enough to cause Barrett's esophagus can almost always be detected on technically adequate double-contrast examinations.

On the basis of these data, the investigators concluded that patients found to be at high risk for Barrett's esophagus on double-contrast esophagograms because of a midesophageal

stricture or ulcer or reticular mucosal pattern should undergo endoscopy and biopsy for a definitive diagnosis.¹⁴⁹ A larger group of patients are found to be at moderate risk for Barrett's esophagus because of reflux esophagitis or peptic strictures in the distal esophagus, so clinical judgment should be used regarding the decision for endoscopy in this group based on the severity of reflux symptoms, age, and overall health of the patient (i.e., whether they are reasonable candidates for endoscopic surveillance). However, most patients are found to be at low risk for Barrett's esophagus because of the absence of esophagitis or strictures, and the risk of Barrett's esophagus is so low in this group that endoscopy does not appear to be warranted. Thus, the major value of double-contrast esophagography is its ability to separate patients into these various risk groups for Barrett's esophagus to determine the relative need for endoscopy and biopsy.

Short-Segment Barrett's Esophagus

Although the radiographic features of long-segment Barrett's esophagus have been well documented, much less is known about the findings in short-segment Barrett's esophagus. In a study by Yamamoto and associates,¹⁵¹ 70% of patients with

Figure 19-27 Barrett's esophagus with a distal stricture. There is a concentric area of narrowing (arrow) in the distal esophagus above a hiatal hernia. An ordinary peptic stricture without Barrett's esophagus could produce identical findings. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 19-28 Other causes of midesophageal strictures. **A.** There is a segmental stricture (arrow) with shallow ulceration in the midesophagus secondary to previous lye ingestion. **B.** There is a smooth, tapered stricture (arrow) in the midesophagus caused by mediastinal irradiation. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

short-segment Barrett's esophagus had esophagitis or peptic scarring or strictures in the distal esophagus on double-contrast esophagograms, but the remaining 30% had hiatal hernias or GER as the only radiographic findings. Thus, the absence of reflux esophagitis or peptic strictures on double-contrast esophagograms does not exclude the possibility of short-segment Barrett's esophagus, and patients with short-segment Barrett's esophagus are far more likely to have a normal-appearing esophagus on double-contrast studies than those with long-segment disease. Nevertheless, the clinical importance of this observation remains uncertain because of the lower cancer risk of short-segment Barrett's esophagus compared with that associated with long-segment disease.^{126,127}

In the study by Yamamoto and co-workers,¹⁵¹ all the patients with short-segment Barrett's esophagus had disease confined to the distal third of the esophagus on barium studies, but the length of involvement of the distal esophagus by esophagitis or peptic scarring often extended more than 3 cm above the gastroesophageal junction, so the diseased segment on esophagography does not necessarily correspond to the vertical extent of columnar metaplasia in the esophagus.

DIFFERENTIAL DIAGNOSIS

Uncomplicated peptic strictures are almost always located in the distal esophagus, so the presence of a midesophageal stricture should strongly suggest the possibility of Barrett's esophagus, particularly if associated with a hiatal hernia and GER. Midesophageal strictures may also be caused by caustic ingestion (Fig. 19-28A), mediastinal irradiation (Fig. 19-28B), and malignant tumors, but these conditions can usually be differentiated from Barrett's esophagus by the clinical history and presentation.

The presence of a reticular mucosal pattern appears to be a relatively specific radiologic sign of Barrett's esophagus, particularly if located adjacent to the distal aspect of a midesophageal stricture.¹⁴² Although a reticulonodular appearance may occasionally be seen in patients with superficial spreading carcinoma, such lesions are not generally associated with strictures.¹⁰¹ *Candida* esophagitis may also be manifested by mucosal nodularity, but the discrete plaquelike lesions of candidiasis can usually be differentiated from the coalescent reticular pattern of Barrett's mucosa.

Other Infections

Because of the increased survival of immunocompromised patients with malignant neoplasms, organ transplants, and other debilitating diseases, infectious esophagitis has become an increasingly common problem in modern medical practice. *Candida albicans* is the usual offending organism, but herpes simplex virus and cytomegalovirus (CMV) have also been recognized with increased frequency as opportunistic esophageal invaders. Patients with AIDS may develop more fulminant forms of fungal and viral esophagitis (including human immunodeficiency virus [HIV] esophagitis), accentuating the need for early diagnosis and treatment.

Candida Esophagitis

PATHOGENESIS

Candidiasis is the most common cause of infectious esophagitis. *C. albicans* is almost always the offending organism.^{1,2} Because *C. albicans* is a commensal inhabitant of the pharynx, *Candida* esophagitis is presumably caused by downward spread of the fungus to the esophagus.³ Clinically significant infection occurs primarily in patients who are immunocompromised because of underlying malignant tumor, debilitating illness, diabetes, or treatment with radiation, steroids, or other cytotoxic agents.^{2,4-7}

Candida esophagitis is particularly prevalent in patients with AIDS, occurring in 15% to 20% of these individuals,⁶ although effective antiviral agents have substantially decreased the number of HIV-positive patients who develop AIDS.

Local esophageal stasis is another factor that predisposes patients to the development of *Candida* esophagitis. Esophageal stasis may be caused by mechanical obstruction from achalasia or strictures or by physiologic obstruction from scleroderma or other causes of esophageal aperistalsis.^{7,8} Delayed esophageal emptying in these patients permits the fungal organism to overgrow and colonize the esophagus with subsequent esophagitis.

Much less frequently, *Candida* esophagitis may develop in otherwise healthy individuals who have no underlying systemic or esophageal diseases.⁹ As a result, the possibility of fungal infection should not be excluded simply because the classic predisposing factors are not present in a particular patient.

CLINICAL FINDINGS

Most patients with *Candida* esophagitis have acute onset of dysphagia or, even more commonly, odynophagia, characterized by intense substernal pain during swallowing.¹⁻⁴ Others may have nonspecific findings such as chest pain, epigastric pain, or upper gastrointestinal bleeding, or they may be asymptomatic.^{1,2,5} Occasionally, patients with chronic *Candida* esophagitis may have persistent dysphagia because of the development of esophageal strictures.¹⁰⁻¹²

Despite the characteristic presentation, *Candida* esophagitis may be difficult to differentiate from viral esophagitis on clinical grounds. The presence of oropharyngeal candidiasis (i.e., thrush) is a helpful finding, but only 50% to 75% of patients with *Candida* esophagitis have fungal lesions in the oropharynx.^{2,13} Other patients with thrush may have herpes or CMV esophagitis, so the presence of oropharyngeal candidiasis does not preclude the development of viral esophagitis.¹⁴ Still other patients may have concomitant *Candida* and herpes esophagitis,^{2,15,16} most likely resulting from fungal superinfection of herpetic ulcers.¹⁶

Immunocompromised patients with *Candida* esophagitis require treatment with potent antifungal agents such as fluconazole.^{2,6,17} Affected individuals usually have a marked clinical response to antifungal therapy. In one study, however, recurrent *Candida* esophagitis occurred in 90% of successfully treated AIDS patients.¹⁸

ENDOSCOPIC FINDINGS

Candida esophagitis is usually characterized at endoscopy by patchy, white exudates covering a friable, erythematous mucosa.^{1,2} In more advanced disease, the mucosa becomes ulcerated and necrotic with extensive pseudomembrane formation. The presence of budding yeast cells, hyphae, and pseudohyphae on endoscopic biopsy specimens with silver stain, periodic

acid–Schiff stain, or Gram stain is diagnostic of *Candida* esophagitis.^{1,2}

RADIOGRAPHIC FINDINGS

Candida esophagitis tends to be a superficial disease with mucosal abnormalities that are difficult to recognize on conventional single-contrast barium studies. As a result, single-contrast esophagography has been an unreliable technique for detecting this condition, with a reported sensitivity of less than 50%.^{1,4,5,9} In contrast, double-contrast esophagography has a sensitivity of about 90% in diagnosing *Candida* esophagitis.^{7,19} The major advantage of this technique is its ability to demonstrate mucosal plaques that cannot easily be seen on single-contrast studies.

Candida esophagitis is usually manifested on double-contrast images by discrete plaquelike lesions consisting of small exudates and pseudomembranes on the mucosa. The lesions tend to be longitudinally oriented, appearing en face as discrete, linear or irregular filling defects with normal intervening mucosa (Fig. 20-1).^{7,14} The plaques are located predominantly in the upper or midesophagus, occasionally having a focal distribution (Fig. 20-2). In the appropriate clinical setting, discrete plaquelike lesions should be highly suggestive of *Candida* esophagitis.

In other patients, *Candida* esophagitis may be manifested by a finely nodular or granular appearance because of tiny plaques

on the mucosa (Fig. 20-3).^{14,20} Some plaques may contain central umbilications that collect barium, mimicking the appearance of tiny ulcers caused by herpes esophagitis.²¹ When larger plaques are present, the lesions may coalesce, producing a distinctive snakeskin appearance (Fig. 20-4).¹⁹ Occasionally, submucosal edema and inflammation may result in thickened longitudinal folds, a nonspecific manifestation of esophagitis.³ Thus, the classic radiographic features of *Candida* esophagitis are not present in all patients.

In severe candidiasis, the esophagus may have a grossly irregular or shaggy contour because of coalescent plaques and pseudomembranes, with trapping of barium between these lesions (Fig. 20-5).^{4,7,14,19,22} Some of these plaques and pseudomembranes may eventually slough, producing one or more deep ulcers superimposed on a background of diffuse plaque formation (see Fig. 20-5B). This fulminant form of candidiasis has been encountered primarily in patients with AIDS.¹⁴ As a result, the shaggy esophagus of *Candida* esophagitis has become a less common finding as more effective antiviral medications have become available to prevent the development of AIDS in HIV-positive patients. Nevertheless, the possibility of AIDS should be suspected when a shaggy esophagus is detected on barium studies, particularly in high-risk patients.

Candida esophagitis may occasionally produce other unusual radiographic findings. In some patients, barium may dissect

Figure 20-1 *Candida* esophagitis with discrete plaques. **A.** Multiple plaquelike lesions are present in the esophagus. The linear plaques have a characteristic appearance with discrete borders and a predominantly longitudinal orientation. **B.** In another patient, the plaques have a more irregular configuration. However, they are still seen as discrete lesions separated by normal mucosa. **C.** The gross specimen in another case shows how these plaquelike lesions represent heaped-up areas of necrotic epithelial debris and actual colonies of *C. albicans* on the mucosa. (**A** and **B** from Levine MS, Macones AJ, Laufer I: *Candida* esophagitis: Accuracy of radiographic diagnosis. *Radiology* 154:581–587, 1985.)

Figure 20-2 Localized *Candida* esophagitis. Discrete plaque-like lesions are clustered together in the midesophagus, with normal-appearing mucosa above and below this level.

Figure 20-3 *Candida* esophagitis with a granular mucosa. This patient has innumerable tiny, nodular elevations in the esophagus rather than the typical plaque-like defects associated with candidiasis.

beneath plaques or pseudomembranes, producing an intramural track or double-barreled esophagus.²² Rarely, a coalescent mass of heaped-up necrotic debris and fungal mycelia (a fungus ball) may be indistinguishable from a polypoid esophageal carcinoma.²³⁻²⁵ Esophageal obstruction, perforation, and tracheoesophageal or aortoesophageal fistula formation are other rare but potentially life-threatening complications.²⁶⁻²⁸

Candida esophagitis usually responds quickly to antifungal therapy, but resolution of the radiographic findings sometimes lags behind the clinical recovery, so follow-up barium studies may still be abnormal in patients who are asymptomatic.²⁴ The immediate effects of antifungal therapy should therefore be assessed primarily on clinical grounds.

Although *Candida* esophagitis is usually self-limited with proper treatment, occasional cases of stricture formation have been reported.¹⁰⁻¹² These strictures typically appear as long, tapered areas of esophageal narrowing (Fig. 20-6).¹² Fungal-induced strictures should be distinguished from pseudostrictures caused by esophageal spasm or the patient's inability to swallow an adequate bolus of barium. Therefore a second examination may be necessary after treatment to determine if a true stricture is present.

Because of the effects of local esophageal stasis (see earlier, "Pathogenesis"), patients with conditions such as achalasia and scleroderma are at increased risk for developing *Candida* esophagitis.^{7,8} Such cases may be manifested on esophagography by tiny nodular defects, polypoid folds, or a distinctive lacy

appearance in the esophagus (Fig. 20-7).⁸ Because of esophageal stasis in patients with achalasia or scleroderma, these individuals may also develop a foamy esophagus characterized by innumerable tiny, rounded bubbles that settle out along the top of the barium column, producing a layer of foam (Fig. 20-8).²⁹ It has been postulated that this finding is caused by extensive production of carbon dioxide by a yeast form of the organism.²⁹ Whatever the explanation, *Candida* esophagitis should be suspected when a foamy esophagus is detected on esophagography, particularly in patients with achalasia or scleroderma.

Candida esophagitis is also known to be associated with esophageal intramural pseudodiverticulosis (see Chapter 21).³⁰⁻³² It has been postulated that the pseudodiverticula develop as a complication of fungal infection.³⁰ It is more widely believed, however, that the fungal organism is a secondary invader as a result of local stasis.^{31,32}

Patients with defects in their cell-mediated immune response to *C. albicans* may have an unusual disease known as chronic mucocutaneous candidiasis, in which there is persistent fungal infection of the skin, mucous membranes, and nails.³³ Although uncommon, esophageal involvement may lead to chronic esophageal candidiasis.³³ In contrast to acute *Candida* esophagitis, this entity is characterized by chronic scarring and stricture formation in the esophagus.³³ The presence of a long esophageal stricture in patients with chronic mucocutaneous candidiasis should therefore suggest the possibility of esophageal involvement by this disease.

Figure 20-4 *Candida* esophagitis with a cobblestone appearance. There is confluent involvement of the mucosa by innumerable round, oval, and polygonal plaques. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

DIFFERENTIAL DIAGNOSIS

Mucosal plaques or nodules may also be caused by herpes esophagitis, reflux esophagitis, glycogenic acanthosis, and superficial spreading carcinoma.^{20,34-39} Although herpes esophagitis is usually manifested by multiple small, discrete ulcers in the esophagus (see later, “*Herpes Esophagitis*”), advanced herpetic infection may lead to the development of plaquelike lesions indistinguishable from those in *Candida* esophagitis (Fig. 20-9).^{34,35}

Reflux esophagitis may also produce a nodular or granular appearance of the mucosa that resembles candidiasis.²⁰ However, the nodules of reflux esophagitis tend to have poorly defined borders that fade peripherally into the adjacent mucosa, whereas the plaques of candidiasis have more discrete borders. The nodular mucosa of reflux esophagitis also occurs as a continuous area of disease, extending proximally from the gastroesophageal junction, whereas *Candida* esophagitis often spares the distal esophagus. Rarely, severe reflux esophagitis may produce inflammatory exudates or pseudomembranes that are indistinguishable on double-contrast studies from the plaquelike lesions of candidiasis.³⁶

Glycogenic acanthosis may also be manifested by discrete plaques or nodules, mimicking the appearance of *Candida* esophagitis.³⁷ However, the nodules of glycogenic acanthosis tend to have a more rounded appearance, whereas the plaques of candidiasis usually have a more linear configuration. The clinical history is also helpful for differentiating these

Figure 20-5 *Candida* esophagitis with a shaggy esophagus. **A, B.** The esophagus has a grossly irregular contour as a result of multiple plaques and pseudomembranes, with trapping of barium between these lesions. A deep area of ulceration (arrow) is also seen (**B**). Both patients had AIDS. (**A** from Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989; **B** from Levine MS, Woldenberg R, Herlinger H, et al: *Opportunistic esophagitis in AIDS: Radiographic diagnosis*. *Radiology* 165:815–820, 1987.)

conditions because patients with glycogenic acanthosis are almost always asymptomatic.³⁷

Superficial spreading carcinoma of the esophagus is characterized by focal nodularity of the mucosa that could be mistaken for a localized area of *Candida* esophagitis.^{38,39} However, candidiasis usually produces discrete plaquelike lesions separated by segments of normal intervening mucosa, whereas the plaques or nodules of superficial spreading carcinoma tend to coalesce, producing a continuous area of disease.^{38,39} Rarely, an advanced infiltrating carcinoma extending longitudinally in the wall can mimic the shaggy esophagus of candidiasis (Fig. 20-10).

Mucosal plaques may be simulated by technical artifacts on double-contrast studies, including air bubbles, debris, and undissolved effervescent agent (Fig. 20-11).^{20,40} When candidiasis is suspected on clinical grounds, double-contrast images of the esophagus should therefore be obtained before administration of an effervescent agent. If the radiographic findings are equivocal, additional double-contrast images may be obtained to demonstrate the transient nature of these artifacts.

Figure 20-6 *Candida*-induced esophageal stricture. A long, tapered stricture is seen in the distal esophagus as a result of scarring from severe *Candida* esophagitis. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 20-7 *Candida* esophagitis in a patient with scleroderma. Tiny nodular defects in the esophagus could be mistaken for retained debris. The esophagus is dilated because of underlying involvement by scleroderma.

Herpes Esophagitis

PATHOGENESIS

Herpes simplex virus type 1, a DNA core virus, has been recognized as another common cause of infectious esophagitis in patients who are immunocompromised because of underlying malignant tumor, debilitating illness, AIDS, or treatment with irradiation, chemotherapy, or steroids.^{14,41-43} This infection should be suspected in the same clinical setting as candidiasis. Occasionally, however, herpes esophagitis may occur as an acute, self-limited disease in otherwise healthy individuals who have no underlying immunologic problems.⁴⁴⁻⁴⁸ Thus, the diagnosis of herpes esophagitis should not be excluded because the patient has a normal immunologic status.

CLINICAL FINDINGS

Patients with herpes esophagitis typically present with acute odynophagia, characterized by severe substernal chest pain during swallowing.^{13,49} Other patients may have dysphagia, chest pain and, less commonly, upper gastrointestinal bleeding.^{50,51} In the appropriate clinical setting, the presence of herpetic lesions in the oropharynx should suggest a diagnosis of herpes esophagitis. Most patients do not have active infection of the oropharynx, however, so the absence of oropharyngeal lesions does not preclude this diagnosis.^{13,49} Furthermore, some patients with herpetic lesions in the oropharynx are found to

have *Candida* esophagitis. As a result, it can be extremely difficult to differentiate viral and fungal esophagitis on clinical grounds.

The natural history of herpes esophagitis is uncertain. In various autopsy series, it has been shown that immunocompromised hosts with herpes esophagitis may develop herpetic pneumonitis or even a disseminated herpetic infection.⁴³ However, most patients with herpes esophagitis recover spontaneously.^{49,52,53} These individuals are usually treated effectively with analgesics and, if necessary, antiviral agents such as acyclovir.⁵⁴

Otherwise healthy patients with herpes esophagitis have a characteristic clinical presentation. They typically are young men with a history of recent exposure to sexual partners with herpetic lesions on the lips or buccal mucosa.^{45,47} Most of these patients have a 3- to 10-day influenza-like prodrome characterized by fever, sore throat, upper respiratory tract infection, and myalgias.^{44,45,47,48} This prodrome is followed by acute onset of odynophagia, which prompts the patient to seek medical attention. Despite the dramatic presentation, these patients almost always have an acute, self-limited illness, with resolution of symptoms in less than 2 weeks.⁴⁴⁻⁴⁷

ENDOSCOPIC FINDINGS

Herpes esophagitis is initially manifested on endoscopy by esophageal vesicles that subsequently rupture to form discrete, punched-out ulcers.^{43,52,53,55} With further progression, the ulcers

Figure 20-8 *Candida* esophagitis with a foamy esophagus in two patients with achalasia. **A, B.** In both cases, innumerable tiny, rounded bubbles are seen to settle out along the top of the barium column, producing a layer of foam (white arrows). Also note tapered narrowing of the distal esophagus (black arrow) caused by underlying achalasia with incomplete opening of the lower esophageal sphincter (**B**).

may become covered by a fibrinous exudate.⁴³ Thus, early herpes esophagitis has a characteristic endoscopic appearance, whereas advanced herpes esophagitis may be indistinguishable from candidiasis. Whatever the stage of infection, the histologic or cytologic findings on endoscopic biopsy specimens or brushings are relatively specific for the herpesvirus group. The classic finding of Cowdry type A intranuclear inclusions in intact epithelial cells adjacent to ulcers is virtually pathognomonic of herpes.⁴³ The diagnosis of herpes esophagitis can also be confirmed by positive viral cultures from the esophagus or by direct immunofluorescent staining for the herpes simplex antigen.²

RADIOGRAPHIC FINDINGS

Herpes esophagitis is usually manifested on double-contrast esophagograms by multiple, small (<1 cm), superficial ulcers in the upper or midesophagus, without plaque formation.^{14,49,56-58} These ulcers are visible on double-contrast images in more than 50% of patients.⁵⁸ The ulcers may have a punctate, linear, ring-like, or stellate configuration and are often surrounded by radiolucent mounds of edema (Fig. 20-12).⁴⁹ Although ulceration may occasionally be seen in advanced *Candida* esophagitis, the ulcers in these patients almost always occur on a background of diffuse plaque formation.^{7,14} Thus, in the appropriate clinical

Figure 20-9 *Herpes* esophagitis. Multiple plaquelike lesions are seen in the midesophagus, mimicking the appearance of candidiasis.

setting, the presence of multiple small, discrete ulcers in the upper or midesophagus should be highly suggestive of herpes esophagitis. Nevertheless, endoscopy may be required for a definitive diagnosis if the radiographic findings are equivocal or if appropriate treatment with antiviral agents fails to produce an adequate clinical response.

More advanced herpes esophagitis may be associated with extensive ulceration, plaque formation, or a combination of ulcers and plaques (see Fig. 20-9).^{34,35,49,56,58} In such cases, the findings may be indistinguishable from those of advanced *Candida* esophagitis. Rarely, herpes esophagitis may be manifested by a giant ulcer, mimicking an ulcerated carcinoma.⁵⁸

Herpes esophagitis in otherwise healthy patients is usually manifested on double-contrast studies by innumerable tiny ulcers that tend to be clustered together in the midesophagus near the level of the left main bronchus (Fig. 20-13).^{59,60} The small size of the ulcers may be related to an intact immune system that contains the herpetic infection and prevents the ulcers from enlarging. Whatever the explanation, the diagnosis of herpes esophagitis in otherwise healthy patients can usually be suggested on the basis of the clinical and radiographic findings.⁶⁰

DIFFERENTIAL DIAGNOSIS

In the appropriate clinical setting, multiple small, discrete ulcers on an otherwise normal background mucosa should be pathognomonic of viral esophagitis. Although most cases are

Figure 20-10 Advanced esophageal carcinoma. The esophagus has a grossly irregular or shaggy contour caused by a highly invasive carcinoma extending longitudinally in the wall. (Courtesy Hans Herlinger, MD, Philadelphia.)

Figure 20-11 Undissolved effervescent agent and bubbles in the esophagus. Although this appearance could be mistaken for *Candida* esophagitis on a single radiograph, the transient nature of these artifacts can easily be confirmed by obtaining additional views.

caused by the herpes simplex virus, CMV may occasionally produce similar findings. However, CMV esophagitis is more commonly manifested by the development of one or more giant ulcers in the esophagus (see later, “[Cytomegalovirus Esophagitis](#)”). Oral medications may also cause a focal contact esophagitis, manifested by multiple small, shallow ulcers indistinguishable from those in herpes esophagitis.^{61,62} The correct diagnosis should be suggested, however, by a temporal relationship between ingestion of the offending medication and the onset of esophagitis. Reflux esophagitis is a common cause of ulceration, but tends to involve the distal esophagus and is usually associated with a hiatal hernia or gastroesophageal reflux. Radiation esophagitis, caustic esophagitis and, rarely, Crohn’s disease involving the esophagus may cause superficial ulceration, but these entities can usually be differentiated from herpes esophagitis by the clinical history and presentation.

Cytomegalovirus Esophagitis

CMV is another member of the herpesvirus group that has been recognized as a cause of infectious esophagitis in AIDS patients.⁶³⁻⁶⁵ For reasons that are unclear, however, CMV esophagitis rarely occurs in other immunocompromised patients. Affected individuals usually present with severe odynophagia. Endoscopic examinations may demonstrate one or more ulcers in the esophagus. Characteristic features of CMV infection on endoscopic biopsy specimens include intranuclear inclusions

and, in contrast to herpes simplex virus, small cytoplasmic inclusions in endothelial cells or fibroblasts at or near the base of the ulcers.^{2,63,65} Endoscopic biopsy specimens, brushings, and viral cultures have a combined sensitivity of greater than 90% in detecting CMV esophagitis.⁶⁶⁻⁶⁸

RADIOGRAPHIC FINDINGS

CMV esophagitis may be manifested on esophagography by discrete, superficial ulcers indistinguishable from those in herpes esophagitis (Fig. 20-14).⁶³⁻⁶⁵ More commonly, however, CMV esophagitis is associated with the development of one or more giant (>1 cm), flat ulcers in the mid or distal esophagus.^{14,63,64,69} These giant ulcers may be recognized in profile or en face as ovoid, elongated, or diamond-shaped collections of barium surrounded by a thin, smooth radiolucent rim of edematous mucosa (Fig. 20-15). Because herpetic ulcers rarely become this large, the presence of one or more giant ulcers should suggest CMV esophagitis in patients with AIDS.

HIV has also been implicated as a cause of giant esophageal ulcers that are impossible to differentiate from CMV ulcers on radiographic criteria (see later, “[Human Immunodeficiency Virus Esophagitis](#)”). Endoscopy is therefore required to distinguish these infections. If endoscopic biopsy specimens or brushings reveal the characteristic cytoplasmic inclusions of CMV, or if viral cultures are positive for CMV, treatment can be initiated with potent antiviral agents such as ganciclovir.^{2,66}

Figure 20-12 Herpes esophagitis with discrete ulcers. **A, B.** Multiple discrete, superficial ulcers are seen in the midesophagus. Many of the ulcers are surrounded by radiolucent mounds of edema. **C.** There are several widely separated ulcers (arrows) with a ringlike or stellate configuration. (**A** from Levine MS: *Radiology of esophagitis: A pattern approach*. Radiology 179:1–7, 1991; **B** courtesy Harvey M. Goldstein, MD, San Antonio, TX.)

However, ganciclovir may cause severe bone marrow suppression with neutropenia, thrombocytopenia, or anemia,^{2,70} so potentially toxic antiviral drugs should be used only if cytopathologic confirmation of CMV is obtained.

Human Immunodeficiency Virus Esophagitis

A clinical syndrome of odynophagia and giant esophageal ulcers has been recognized in patients with HIV infection.^{71–78} Biopsy specimens, brushings, and cultures from the esophagus have failed to reveal any signs of the usual fungal or viral organisms associated with infectious esophagitis in patients with AIDS. Furthermore, electron microscopy of biopsy specimens from these ulcers has demonstrated viral particles with morphologic features of HIV infection, directly implicating HIV as the cause of the ulcers.⁷⁴ These HIV ulcers (also called idiopathic ulcers^{76,77}) may develop in patients who have recently become HIV-positive or in patients who have been HIV-positive for extended periods and have other clinical signs of AIDS.^{2,73–76,78} Thus, giant esophageal ulcers may occur as a manifestation of acute or chronic HIV infection.

CLINICAL FINDINGS

Patients with HIV ulcers in the esophagus typically present with acute onset of severe odynophagia.^{72–76,78} The pain may be so intense that patients are unable to swallow their saliva.

Occasionally, these patients may develop hematemesis or other signs of upper gastrointestinal bleeding.⁷¹ The ulcers sometimes develop at or shortly after the time of HIV seroconversion.⁷⁴ As part of this seroconversion syndrome, there may be associated ulcers in the oropharynx and soft palate or a characteristic maculopapular rash involving the face, trunk, and upper extremities.^{72,73,76} In most cases, however, HIV ulcers in the esophagus occur after the patient has developed clinically overt AIDS with low CD4 counts.^{2,78}

Candida, herpes, and CMV esophagitis are other common causes of odynophagia in HIV-positive patients, but the possibility of HIV esophagitis should be suspected if these individuals have the characteristic maculopapular rash or develop symptoms at or near the time of seroconversion. HIV can sometimes be confirmed as the cause of the ulcers by electron microscopy and in situ DNA hybridization.^{74,76} Because these techniques are not widely available, however, HIV esophagitis has primarily been a diagnosis of exclusion when no cytopathologic findings of CMV or other opportunistic infections are present on endoscopic biopsy specimens or brushings.^{71,75,77,78}

RADIOGRAPHIC FINDINGS

HIV esophagitis is usually manifested on esophagography by the development of one or more giant (>1 cm), flat ulcers in the mid or distal esophagus, sometimes associated with small, satellite ulcers (Fig. 20-16).^{75,78} The ulcers may appear in profile or en face as ovoid, elongated, or diamond-shaped collections

Figure 20-13 Herpes esophagitis in an otherwise healthy patient. Multiple punctate and linear areas of ulceration are seen in the midesophagus below the level of the left main bronchus. This appearance is characteristic of herpes esophagitis in immunocompetent patients. (From DeGaeta L, Levine MS, Guglielmi GE, et al: *Herpes esophagitis in an otherwise healthy patient*. *AJR* 144:1205–1206, 1985.)

of barium, often surrounded by a thin, smooth radiolucent rim of edema.^{75,78} These HIV ulcers are therefore indistinguishable radiographically from CMV ulcers in the esophagus (see Fig. 20-15).^{75,78} Nevertheless, most giant esophageal ulcers in HIV-positive patients are caused by HIV rather than CMV.⁷⁸ In contrast to CMV ulcers, HIV ulcers in the esophagus may heal spontaneously or may respond to treatment with steroids, but do not require treatment with potentially toxic antiviral agents such as ganciclovir.^{2,72-74,78,79} Endoscopic biopsy specimens, brushings, and viral cultures are therefore required to differentiate HIV ulcers from CMV ulcers, so appropriate treatment can be instituted in these patients.

Rarely, HIV esophagitis may be associated with the development of esophagoesophageal or esophagogastric fistulas or focal perforation into the mediastinum.⁸⁰ Tuberculous esophagitis can also be associated with intramural sinus tracks and fistulas, but these tracks and fistulas tend to be located more proximally in the esophagus in patients with tuberculosis (see later, “**Tuberculosis**”).^{81,82} Other causes of giant ulcers include nasogastric intubation, endoscopic sclerotherapy, caustic ingestion, and oral medications such as quinidine, potassium chloride, and nonsteroidal anti-inflammatory drugs. The correct diagnosis is usually suggested by the clinical history and presentation. Thus, for all practical purposes, giant esophageal ulcers in HIV-positive patients are almost always caused by HIV or CMV.

Figure 20-14 Cytomegalovirus esophagitis. Multiple discrete, superficial ulcers are seen in the midesophagus. Herpes esophagitis could produce identical radiographic findings. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Tuberculosis

Esophageal involvement by tuberculosis is extremely uncommon. When it occurs, these patients usually have advanced tuberculosis in the lungs or mediastinum.^{83,84} Both *Mycobacterium tuberculosis* and *Mycobacterium avium-intracellulare* have been implicated as causes of infectious esophagitis in patients with AIDS.^{81,82}

Esophageal involvement is usually caused by adjacent tuberculous nodes in the mediastinum that compress or erode into the esophagus, causing narrowing, ulceration, or fistula formation.^{81,84,85} In patients with active pulmonary tuberculosis, esophageal infection may also be caused by swallowed sputum containing the tubercle bacilli, particularly if there is a preexisting mucosal lesion or stricture in the esophagus. Rarely, hematogenous seeding of the esophagus may occur in patients with disseminated miliary tuberculosis.

Patients with tuberculous esophagitis may be asymptomatic, or they may present with dysphagia, odynophagia, or chest pain.⁸⁴ Although the clinical findings are nonspecific, the possibility of esophageal tuberculosis should be considered in patients with persistent dysphagia who have active pulmonary tuberculosis. In such cases, the diagnosis may be confirmed at endoscopy by the presence of tubercle bacilli or, rarely, caseating granulomas on endoscopic biopsy specimens or brushings from the esophagus.⁸⁶

Figure 20-15 Cytomegalovirus esophagitis. **A.** A giant, relatively flat ulcer (arrows) is seen in profile in the distal esophagus. **B.** A large, ovoid ulcer (arrows) is seen en face in another patient. Note the thin radiolucent rim of edema surrounding the ulcer. Because herpetic ulcers rarely become this large, the presence of one or more giant esophageal ulcers should raise the possibility of cytomegalovirus esophagitis in patients with AIDS. (**A** courtesy Sidney W. Nelson, MD, Seattle; **B** courtesy Kyunghee C. Cho, MD, Newark, NJ.)

Figure 20-16 Human immunodeficiency virus (HIV) esophagitis. **A.** A giant, relatively flat ulcer (arrows) is seen in profile in the distal esophagus. This patient was HIV-positive. **B.** In another HIV-positive patient, a large ovoid ulcer (arrows) is seen en face with a thin surrounding rim of edema. **C.** In a third patient, a diamond-shaped ulcer (arrows) is seen in the midesophagus with a cluster of small satellite ulcers. All three cases are indistinguishable from the cytomegalovirus ulcers illustrated in [Figure 20-15](#). However, endoscopic biopsy specimens, brushings, and cultures were negative for cytomegalovirus in these patients. (From Levine MS, Loercher G, Katzka DA, et al: Giant, human immunodeficiency virus-related ulcers in the esophagus. *Radiology* 180:323–326, 1991.)

Figure 20-17 Tuberculous esophagitis. There is compression (black arrows) of the upper thoracic esophagus with associated ulceration (white arrow) caused by caseating tuberculous nodes that have eroded into the esophagus. (Courtesy Alan Grundy, MD, London.)

Figure 20-18 Tuberculous esophagitis in a patient with AIDS. There is diffuse esophagitis with several deep sinus tracks (arrows) extending anteriorly from the esophagus into the mediastinum. (From Goodman P, Pinero SS, Rance RM, et al: *Mycobacterial esophagitis in AIDS*. *Gastrointest Radiol* 14:103–105, 1989.)

RADIOGRAPHIC FINDINGS

Extrinsic esophageal involvement by tuberculous nodes in the mediastinum is usually manifested on esophagography by compression, displacement, or narrowing of the esophagus by an adjacent mediastinal mass.^{83,85,86} These patients may also develop strictures or traction diverticula, usually at the level of the carina.^{83,84} Occasionally, caseating nodes in the mediastinum may erode into the upper or midesophagus, producing superficial or deep areas of ulceration, longitudinal or transverse sinus tracks, or fistulas into the mediastinum or tracheobronchial tree (Fig. 20-17).^{83–85} Sinus tracks and fistulas have been recognized as particularly prominent features of tuberculous esophagitis in patients with AIDS (Fig. 20-18).^{81,82} Similar findings may be demonstrated in patients with Crohn's disease, trauma, radiation, and esophageal carcinoma, but the presence of pulmonary or mediastinal tuberculosis should suggest the correct diagnosis, particularly in patients with AIDS.

Intrinsic tuberculous esophagitis occurs much less frequently and is characterized on barium studies by mucosal irregularity, ulcers, plaques, fistulas and, eventually, strictures (Fig. 20-19).^{83,86} Rarely, esophageal tuberculosis can lead to the development of an intramural abscess, seen on esophagography as a smooth submucosal mass and on computed tomography (CT) as a well-margined cystic mass with an enhancing rim in the esophagus.⁸⁷ Tuberculous esophagitis

may be indistinguishable from severe esophagitis resulting from caustic ingestion, radiation, or other causes.

Actinomycosis

Actinomycosis is an indolent, suppurative infection caused by *Actinomyces israelii*, an anaerobic, gram-positive bacterium. Rarely, this organism may cause severe esophagitis in patients with AIDS.⁸⁸ Esophageal actinomycosis may be manifested on esophagography by deep ulcers with multiple longitudinal and transverse fistulas and intramural tracks (Fig. 20-20).⁸⁸ Although tuberculous esophagitis may also cause ulceration and fistula formation (see earlier, “Tuberculosis”), the presence of multiple intramural tracks parallel to the esophageal lumen should raise the possibility of esophageal actinomycosis in patients with AIDS.

Other Infections

Although infectious esophagitis is usually caused by fungal or viral organisms, other rare causes include *Staphylococcus*, *Streptococcus*, *Klebsiella*, *Blastomyces*, *Cryptosporidium*, *Torulopsis glabrata*, and *Lactobacillus acidophilus*.^{89–94}

Figure 20-19 Tuberculous esophagitis. **A.** The initial esophagogram shows two areas of irregular ulceration (arrows) in the midesophagus caused by proven tuberculous esophagitis. **B.** Another esophagogram after 6 months of antituberculous therapy shows healing of the ulcers. Drug-Induced Esophagitis

Since its original description in 1970,¹ drug-induced esophagitis has been recognized as a relatively common condition in today's pill-oriented society. The medications implicated most frequently include tetracycline, doxycycline, potassium chloride, quinidine, aspirin, other nonsteroidal anti-inflammatory drugs (NSAIDs), and alendronate sodium. These patients may have severe esophageal symptoms, but drug-induced esophagitis usually resolves after withdrawal of the offending agent. Although conventional single-contrast barium studies have limited value in detecting mucosal abnormalities associated with drug-induced esophagitis, double-contrast esophagography is a valuable technique for diagnosing this condition.

PATHOGENESIS

The type and degree of injury that occurs in drug-induced esophagitis depend not only on the properties of the

offending medication but also on the manner in which it is taken. Many patients have a history of ingesting the medication with little or no water before going to bed.²⁻⁴ As a result, the tablets or capsules may become lodged in the midesophagus, where they are compressed by the adjacent aortic arch or left main bronchus.² Drug-induced esophagitis is therefore believed to represent a focal contact esophagitis, with injury to the adjacent mucosa by the dissolving pills. Less frequently, prolonged retention of the medication may result from esophageal compression by an enlarged heart.⁵ Occasionally, drug-induced esophagitis may be caused by abnormal motility or preexisting strictures that delay transit of pills from the esophagus.^{6,7}

CAUSATIVE AGENTS*Tetracycline and Doxycycline*

Tetracycline and doxycycline, two widely used antibiotics, are responsible for at least 50% of all cases of drug-induced

esophagitis.² Because these medications are given in the form of capsules that are relatively acidic, prolonged retention of the capsules in the upper or midesophagus may cause superficial ulceration of the adjacent mucosa.^{2,8} Although doxycycline (pH 3.0) is slightly less acidic than tetracycline (pH 2.3), it dissolves more slowly and forms an adherent gel, presumably accounting for the high frequency of esophagitis in patients taking this agent.⁹ Affected individuals almost never develop strictures, however, because the ulcers caused by tetracycline and doxycycline are so small and superficial that they rarely cause enough scarring and fibrosis to produce a stricture.⁴

Potassium Chloride

Potassium chloride tablets may produce a severe form of drug-induced esophagitis.^{1,2,5,10-12} These patients often have mitral valvular disease with an enlarged left atrium compressing the distal esophagus, so passage of the potassium chloride tablets is impeded at this level. Subsequent release of potassium chloride over a localized area of esophageal mucosa may cause severe chemical injury with focal ulceration and stricture formation.^{5,11,12} As a result, potassium supplements are sometimes given in liquid form to patients with known cardiomegaly to prevent this complication. Even liquid potassium, however, has been described as a cause of drug-induced esophagitis.¹³

Quinidine

Because oral quinidine is often given for cardiac arrhythmias, these patients may have associated cardiomegaly, with compression of the distal esophagus by an enlarged left atrium or ventricle. Retained quinidine above this level may have a corrosive effect on the adjacent mucosa, causing ulceration and strictures.^{2,6,13}

Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) have been implicated with increasing frequency in the development of esophagitis. Major offending agents include aspirin, phenylbutazone, indomethacin (Indocin), ibuprofen (Motrin), naproxen (Naprosyn), piroxicam (Feldene), and sulindac (Clinoril).^{2,14-19} These NSAIDs not only may cause a focal contact esophagitis, but sometimes may lead to stricture formation.^{15,16}

Alendronate

Alendronate sodium (Fosamax) is an aminobisphosphonate, a selective inhibitor of osteoclast-mediated bone resorption, that has been used with increasing frequency in the non-hormonal treatment of postmenopausal osteoporosis. This agent may be associated with the development of a severe form of ulcerative esophagitis and stricture formation in the distal esophagus.²⁰⁻²³ The mechanism of injury is uncertain. Topical corrosive injury may be a contributing factor, but the high frequency of ulceration in the distal esophagus suggests that there is a reflux-mediated component in these patients.²⁰

Other Drugs

Other oral medications that have been implicated in the development of drug-induced esophagitis include emepronium bromide, ferrous sulfate, alprenolol chloride, ascorbic acid, theophylline, cromolyn sodium, and antibiotics such as clindamycin and lincomycin.^{2,7,24-29}

CLINICAL FINDINGS

Patients with drug-induced esophagitis typically present with odynophagia or unremitting chest pain accentuated by swallowing.² Others may present with signs of upper gastrointestinal (GI) bleeding.^{7,19} Symptoms usually develop within several hours to days after taking the medication.² The symptoms of drug-induced esophagitis also tend to resolve rapidly after withdrawal of the offending agent, so most patients are asymptomatic within 7 to 10 days after stopping the medication.⁸ Occasional patients may have progressive dysphagia because of the development of strictures.^{11,13,30}

RADIOGRAPHIC FINDINGS

The radiographic findings in drug-induced esophagitis depend on the nature of the offending medication. Tetracycline, doxycycline and, less commonly, other medications cause superficial ulceration in the esophagus without permanent sequelae. Double-contrast esophagography is a useful technique for detecting shallow ulcers that cannot easily be recognized on single-contrast studies. Affected individuals may have a solitary ulcer (Fig. 21-1A), several discrete ulcers (Fig. 21-1B), or multiple small ulcers on a normal background mucosa (Fig. 21-1C).^{4,31-33} The ulcers are usually clustered together in the midesophagus near the level of the aortic arch or left main bronchus. These ulcers may be recognized en face as punctate, linear, ovoid, stellate, or serpiginous collections of barium or in profile as shallow depressions (see Fig. 21-1).^{4,31-33} When esophageal ulcers are drug induced, a follow-up esophagogram 7 to 10 days after withdrawal of the offending agent often shows dramatic healing of the lesions.³¹

Potassium chloride, quinidine, NSAIDs, and alendronate tend to cause a more severe form of esophagitis, sometimes associated with stricture formation. Potassium chloride and quinidine may result in particularly large ulcers with considerable surrounding edema and inflammation, mimicking the appearance of an ulcerated carcinoma (Fig. 21-2A).^{13,31,34} Subsequent scarring and fibrosis occasionally lead to the development of strictures that typically appear as segmental areas of concentric narrowing above the level of an enlarged left atrium (Fig. 21-2B).^{5,12,13,18,30} In contrast, aspirin and other NSAIDs sometimes produce giant, flat ulcers that are several centimeters or longer (Fig. 21-3A).¹⁷ Healing of these ulcers may result in smooth, re-epithelialized depressions that are sometimes mistaken for active ulcer craters (Fig. 21-3B).¹⁷ Finally, alendronate may be associated with the development of severe ulcerative esophagitis and stricture formation in the distal esophagus (Fig. 21-4).²⁰⁻²²

DIFFERENTIAL DIAGNOSIS

Herpes esophagitis is the major consideration in the differential diagnosis for discrete, superficial ulcers in the upper or midesophagus.³⁵ Although viral ulcers may be indistinguishable from the ulcers of drug-induced esophagitis, the correct diagnosis can usually be suggested on the basis of the clinical history. Occasionally, however, herpes esophagitis may occur in otherwise healthy individuals who have no underlying immunologic problems (see Chapter 20).³⁶ The diagnosis of drug-induced esophagitis should therefore be

Figure 21-1 Drug-induced esophagitis with superficial ulcers. **A.** A solitary ringlike ulcer (arrows) is seen in the midesophagus. Note the thin radiolucent halo of edematous mucosa surrounding the ulcer. **B.** Several discrete ulcers (arrows) are seen in the midesophagus on a normal background mucosa. The largest ulcer has a stellate configuration. **C.** This patient has a flat ulcer (white arrow) on the right lateral wall of the midesophagus, with a cluster of small ulcers (black arrows) abutting the larger ulcer. The patient in **A** was taking doxycycline, the patient in **B** was taking tetracycline, and the patient in **C** was taking ibuprofen. (**A** and **B** from Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

considered only when there is a definite temporal relationship between ingestion of the offending medication and the onset of esophagitis.

Reflux esophagitis is a more common cause of superficial ulceration, but the ulcers are almost always confined to the distal esophagus.³⁷ Mediastinal irradiation and caustic ingestion are other causes of ulceration, but the correct diagnosis is usually suggested on clinical grounds. Crohn's disease may also be associated with shallow ulcers in the esophagus, but these patients usually have advanced Crohn's disease in the small bowel or colon (see later, "[Crohn's Disease](#)"). Finally, giant drug-induced ulcers may be indistinguishable from ulcerated carcinomas or from cytomegalovirus or human immunodeficiency virus (HIV) ulcers in patients with AIDS (see Chapter 20).³⁸ However, these conditions can usually be differentiated by the clinical history and presentation.

Because drug-induced strictures are usually located at a considerable distance from the gastroesophageal junction, they must be differentiated from high esophageal strictures caused by Barrett's esophagus, mediastinal irradiation, caustic ingestion, eosinophilic esophagitis, and primary or metastatic tumors. However, the possibility of a drug-induced stricture should be suspected in patients with cardiomegaly who have a history of taking potassium chloride or quinidine.

Radiation Esophagitis

Malignant tumors involving the lungs, mediastinum, or thoracic spine are often treated by high-dose, external-beam radiation to the chest. The major limiting factor with this form of treatment is esophageal damage by ionizing radiation. Total doses of 45 to 60 Gy may lead to severe esophagitis, with irreversible damage and stricture formation.³⁹ Smaller doses (20 to 45 Gy) may cause a self-limited esophagitis without permanent sequelae. Most patients have clinical evidence of esophagitis shortly after the onset of radiation therapy, but barium studies are not usually performed during this period. Instead, esophagography has been used primarily to detect strictures or other signs of chronic radiation injury. Both the acute and the chronic forms of radiation esophagitis are considered in this chapter.

PATHOGENESIS

Experiments on laboratory animals have shown that high-dose radiation to the esophagus causes an acute, self-limited form of esophagitis within 1 to 3 weeks of the onset of radiation therapy.^{40,41} After the acute stage of radiation injury and subsequent epithelial repair, chronic radiation esophagitis is characterized by progressive submucosal scarring and fibrosis with

Figure 21-2 Spectrum of esophageal injury associated with potassium chloride ingestion. **A.** A giant ulcer (white arrows) is seen in the midesophagus with an associated area of mass effect (black arrows) caused by a surrounding mound of edema. This lesion could be mistaken for an ulcerated carcinoma. **B.** A midesophageal stricture (arrows) is seen in another patient who had been taking slow-release potassium chloride tablets. The stricture has relatively tapered borders. (B from Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

the development of esophageal strictures 4 to 8 months after completion of radiation therapy at doses of 30 to 50 Gy.⁴² If the radiation dose is more than 60 Gy, esophageal strictures may develop within 3 to 4 months.⁴²

CLINICAL FINDINGS

Most patients who receive mediastinal irradiation develop a self-limited esophagitis, manifested by acute onset of substernal burning, odynophagia, or dysphagia within 1 to 3 weeks after the onset of radiation therapy.⁴³ The symptoms usually subside within 24 to 48 hours but may occasionally persist for several weeks.⁴³ Because these patients are immunocompromised, the development of odynophagia may erroneously be attributed to opportunistic esophagitis. The correct diagnosis should be suggested, however, by the temporal relationship between the onset of radiation therapy and onset of symptoms. When acute radiation esophagitis is suspected, these patients are usually treated empirically with viscous lidocaine and analgesics, so radiologic or endoscopic examinations are not often performed in this setting.

Chronic radiation injury to the esophagus may cause dysphagia within several months after completion of radiation therapy. Dysphagia may result from esophageal dysmotility or,

Figure 21-3 Drug-induced esophagitis with a giant esophageal ulcer. **A.** Initial double-contrast esophagogram shows a 7-cm-long, diamond-shaped ulcer (arrows) in the midesophagus below the level of the carina. The ulcer crater has irregular margins. This patient was taking sulindac (Clinoril), a nonsteroidal anti-inflammatory agent. **B.** Another esophagogram 6 months later shows a long, shallow depression with smooth borders (arrows) at the site of the previous ulcer. Endoscopy revealed that this was an ulcer scar with a re-epithelialized pit or depression. (From MS Levine, RD Rothstein, I Laufer: *Giant esophageal ulcer due to Clinoril*. *AJR* 156:955-956, 1991.)

less commonly, from the development of strictures.^{39,42} Mild radiation strictures may be successfully dilated, but more severe strictures necessitate feeding tube placement or other palliative measures. Occasionally, severe radiation injury may lead to life-threatening complications such as an esophageal airway fistula or esophageal perforation. However, these unusual complications of radiation therapy almost always occur in an area of the esophagus involved by tumor and rarely in normal irradiated tissue.^{42,44}

RADIOGRAPHIC FINDINGS

Although most patients with acute radiation esophagitis are treated empirically, barium studies are sometimes performed when the clinical diagnosis is uncertain. This condition may be manifested on double-contrast esophagography by a granular appearance of the mucosa and decreased distensibility from edema and inflammation of the irradiated segment (Fig. 21-5A).⁴⁵ Other patients with acute radiation esophagitis have multiple small, discrete ulcers within a known radiation portal (Fig. 21-6).^{41,45} With more severe disease, the esophagus may have a grossly irregular, serrated contour secondary to larger areas of ulceration and mucosal sloughing.

After the acute phase of radiation injury, the most frequent finding on barium studies is abnormal esophageal motility, which usually develops 4 to 8 weeks after completion of radiation therapy.^{39,42,46} This dysmotility is characterized by interruption of primary peristalsis at the superior border of the

Figure 21-4 Alendronate-induced esophagitis. Multiple tiny ulcers (arrows) are seen in profile in the distal esophagus. This patient was taking alendronate (Fosamax) for the treatment of postmenopausal osteoporosis. (Courtesy Barbara Sabinsky, MD, Stamford, CT.)

radiation portal, with numerous nonperistaltic contractions distal to the point of disruption of the primary wave.^{39,42,46} Less commonly, the irradiated segment may be aperistaltic.⁴²

Radiation strictures in the esophagus usually develop 4 to 8 months after completion of radiation therapy.^{39,42} Higher doses of radiation may shorten the interval for developing a stricture but have no effect on its length or caliber. The strictures typically appear as relatively smooth, tapered areas of concentric narrowing in the upper or midesophagus within a preexisting radiation portal (Fig. 21-5B).^{39,42,44}

Tracheoesophageal and esophagobronchial fistulas are potentially life-threatening complications of mediastinal irradiation. These fistulas are usually caused by radiation necrosis, with erosion of tumor into the esophagus and adjacent airway.⁴⁴ The most frequent site of fistula formation is the left main bronchus, where it crosses the esophagus at the level of the fourth or fifth thoracic vertebra.⁴² When an esophageal airway fistula is suspected, the radiologic examination should be performed with barium sulfate because a water-soluble contrast agent may cause severe pulmonary edema if it enters the lungs via a fistula.⁴⁷

DIFFERENTIAL DIAGNOSIS

When acute odynophagia or dysphagia develops several weeks after mediastinal irradiation, the major diagnostic considerations are acute radiation esophagitis versus infectious esophagitis in an immunocompromised patient. *Candida*

Figure 21-5 Acute radiation esophagitis with subsequent stricture formation. **A.** The mucosa has a granular appearance in the upper thoracic esophagus. Also note decreased distensibility of the irradiated segment. The patient presented with acute odynophagia 3 weeks after undergoing mediastinal irradiation for bronchogenic carcinoma. **B.** Another esophagogram 6 months later because of recurrent dysphagia shows a smooth, tapered stricture within the radiation portal.

esophagitis should be suggested on barium studies by mucosal plaques, whereas herpes esophagitis should be suggested by discrete superficial ulcers without plaque formation.³⁵ In contrast, radiation esophagitis may be manifested by a granular appearance or ulceration, but the area of involvement almost always conforms to a known radiation portal, with a sharp demarcation at the superior and inferior borders of the portal (see Fig. 21-6).

Although many conditions should be considered in the differential diagnosis for an upper or midesophageal stricture,⁴⁸ the major considerations after mediastinal irradiation should be a radiation stricture versus esophageal involvement by recurrent mediastinal tumor (see Chapter 24). A concentric area of smooth, tapered narrowing should favor the diagnosis of a radiation stricture, whereas irregular, eccentric narrowing with extrinsic mass effect should suggest a malignant tumor. When the radiographic findings are equivocal, computed tomography (CT) may be helpful for differentiating a radiation stricture from recurrent tumor in the mediastinum.

Caustic Esophagitis

Caustic esophagitis did not become a serious medical problem in the United States until 1967, when concentrated liquid lye

Figure 21-6 Acute radiation esophagitis. Multiple superficial ulcers are seen en face and in profile (white arrows) in the midesophagus. The area of ulceration has a relatively abrupt inferior demarcation (black arrows), which corresponds to the lower border of the radiation portal. This patient had undergone mediastinal irradiation for bronchogenic carcinoma several weeks earlier. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

solutions were made commercially available to the U.S. public for use as drain cleaners.⁴⁹ Because they could be swallowed rapidly, liquid corrosives exposed all surfaces of the upper GI tract to potentially life-threatening caustic injury. Thus, caustic esophagitis became an important clinical entity. Endoscopy has generally been advocated as the best means of assessing the extent and severity of esophageal injury, but radiologic studies may also provide valuable information during the acute and chronic stages of the disease.

PATHOGENESIS

Caustic injury to the esophagus may be caused by ingestion of alkali, acids, ammonium chloride, phenols, silver nitrate, and a variety of other common household products. Children usually ingest these corrosive substances accidentally, whereas adults take them intentionally to commit suicide. The degree of injury depends on the nature, concentration, and volume of the corrosive agent as well as the duration of tissue contact. In the United States, most patients with caustic esophagitis swallow some form of liquid lye (concentrated sodium hydroxide), which causes severe esophageal injury by liquefaction necrosis.^{50,51} In contrast, ingested acids cause tissue damage by coagulative necrosis, forming a protective eschar that tends to limit

further tissue penetration.^{50,51} Nevertheless, acidic agents may produce severe esophagitis and strictures comparable to those caused by lye.⁵²

Caustic esophagitis is characterized pathologically by three phases of injury—an acute necrotic phase, an ulceration-granulation phase, and a final phase of cicatrization and scarring.⁵³ The initial phase of acute cellular necrosis begins immediately after caustic ingestion. This acute phase usually lasts 1 to 4 days and is accompanied by an intense inflammatory reaction in the surrounding tissues.⁵³ The ulceration-granulation phase begins 3 to 5 days after caustic ingestion and is characterized by edema, ulceration, and sloughing of necrotic mucosa.⁵³ During the next 7 to 14 days, subsequent healing leads to the production of granulation tissue in areas of mucosal sloughing. The esophagus is thought to be weakest and therefore most vulnerable to perforation during this period. The final phase of cicatrization begins 3 to 4 weeks after caustic ingestion.⁵³ Depending on the degree of injury, this cicatrization process may lead to severe scarring and stricture formation.

CLINICAL FINDINGS

Acute caustic esophagitis may be manifested by odynophagia, chest pain, drooling, vomiting, or hematemesis.^{50,51,53} Severe substernal pain, fever, and shock usually indicate esophageal perforation and mediastinitis.^{50,51} Associated gastric perforation leads to the development of peritonitis. If patients survive the acute illness, there may be a latent period of several weeks, during which they are no longer symptomatic.^{50,51,53} Subsequently, however, these patients often develop severe dysphagia secondary to progressive stricture formation 1 to 3 months after the initial injury.^{50,51}

DIAGNOSIS AND TREATMENT

When caustic ingestion is suspected, examination of the mouth and oropharynx sometimes reveals obvious tissue injury, with ulceration of the lingual, buccal, or pharyngeal mucosa. Liquid corrosives may be swallowed rapidly, however, so caustic esophagitis often occurs without associated pharyngeal injury.^{50,51,53} Direct visualization of the esophagus is therefore required to confirm this diagnosis. A limited radiographic study may be performed with a water-soluble contrast agent to detect an esophageal or gastric perforation or other signs of caustic injury. However, most authors advocate endoscopy within 24 hours of caustic ingestion (assuming that there are no clinical or radiographic signs of perforation) to assess the extent and severity of esophageal injury.^{50,51,53}

Treatment of caustic esophagitis is generally aimed at preventing stricture formation. Some advocate early administration of steroids and antibiotics to inhibit collagen formation and decrease the risk of infection.^{54,55} Others believe that esophageal bougienage should be performed as early as 2 to 3 weeks after caustic ingestion. Despite such measures, 10% to 40% of patients with caustic esophagitis develop strictures.^{51,56} Some of these strictures may respond to periodic dilation procedures, but others eventually require an esophageal bypass operation, such as a colonic interposition (see Chapter 27). When strictures develop after caustic ingestion, barium studies may be used to determine the degree and extent of stricture formation as well as the response to treatment. Patients with lye strictures are also thought to have a substantially

increased risk of developing esophageal carcinoma 20 to 40 years after the initial caustic injury.^{57,58} This subject is discussed in detail in Chapter 23.

RADIOGRAPHIC FINDINGS

Chest and abdominal radiographs should be obtained routinely for patients who have ingested caustic agents. With severe esophageal injury, posteroanterior and lateral radiographs of the chest may show a dilated, gas-filled esophagus or, if esophageal perforation has occurred, mediastinal widening, pneumomediastinum, or pleural effusions.^{59,60} Similarly, abdominal radiographs may reveal pneumoperitoneum or a localized gas-containing abscess from gastric perforation.

When esophageal or gastric perforation is suspected in patients who have normal or equivocal chest and abdominal radiographs, a water-soluble contrast study should be performed to document the presence of a leak. Water-soluble contrast agents are used because barium in the mediastinum may cause mediastinal fibrosis, and barium in the peritoneal cavity may cause peritonitis.⁴⁷ If there is no evidence of esophageal or gastric perforation with a water-soluble contrast agent, however, barium should be given for a more detailed examination.

Acute caustic esophagitis may be manifested on esophagography by esophageal dysmotility with poor primary peristalsis, nonperistaltic contractions, diffuse esophageal spasm, or a dilated, atonic esophagus (Fig. 21-7).⁵⁹⁻⁶² Some authors believe

that the latter finding indicates diffuse muscular necrosis and that it is an ominous sign of impending esophageal perforation.⁵⁹ These various motor abnormalities have been attributed to edema, inflammation, or destruction of ganglion cells in Auerbach's plexus.^{61,63}

In other patients, acute caustic esophagitis may be manifested by multiple shallow, irregular ulcers (Fig. 21-8). With more severe caustic injury, the esophagus may be diffusely narrowed and may have a grossly irregular contour because of marked edema, spasm, and ulceration (Fig. 21-9).^{52,59,60} Occasionally, contrast material may dissect beneath partially sloughed mucosal fragments, producing a double-barreled appearance.⁵⁹

Subsequent cicatrization and fibrosis may lead to the development of one or more strictures in the esophagus 1 to 3 months after the acute injury. The strictures usually appear as relatively long areas of smooth, tapered narrowing in the upper or midesophagus; some strictures may have an irregular contour or eccentric areas of sacculation because of asymmetric scarring (Fig. 21-10).⁶⁰ With severe scarring, the entire thoracic esophagus may have a threadlike, filiform appearance (Fig. 21-11).⁶⁰ This finding should be highly suggestive of a caustic stricture because other conditions are rarely associated with such severe esophageal narrowing. When esophagography is performed after caustic ingestion, the stomach should also be evaluated to determine whether associated gastric injury is present. This subject is discussed in detail in Chapter 30.

Figure 21-7 Acute caustic esophagitis with a dilated, atonic esophagus. There is a dilated, aperistaltic, gas-filled esophagus with a small amount of water-soluble contrast material in the stomach. This finding indicates a high risk of perforation.

Figure 21-8 Acute caustic esophagitis. Multiple shallow, irregular ulcers are seen en face and in profile in the midesophagus. This patient had taken concentrated potassium hydroxide in a suicide attempt. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 21-9 Severe caustic esophagitis. The thoracic esophagus is diffusely narrowed and has a grossly irregular contour with extensive ulceration because of ingestion of concentrated sodium hydroxide (liquid lye). (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 21-10 Lye strictures. A long, tapered stricture (black arrows) is seen in the upper thoracic esophagus. Another short, asymmetric stricture (white arrow) is seen more proximally at the thoracic inlet. The presence of one or more segmental strictures in the cervical or thoracic esophagus is characteristic of caustic injury. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

DIFFERENTIAL DIAGNOSIS

Acute caustic esophagitis may be difficult to differentiate from severe cases of reflux, infectious, drug-induced, or radiation esophagitis. However, reflux esophagitis tends to involve the distal esophagus, drug-induced esophagitis usually involves the midesophagus, and radiation esophagitis occurs within a pre-existing radiation portal. In contrast, the site of caustic injury in the esophagus is unpredictable because these patients may have segmental or diffuse esophagitis involving the cervical or thoracic esophagus. Whatever the radiographic findings, the diagnosis of caustic esophagitis is usually apparent from the clinical history.

The classic finding of a long, tapered stricture in the cervical or thoracic esophagus should suggest prior caustic ingestion. However, localized caustic strictures in the upper or mid-esophagus may be indistinguishable from high esophageal strictures from other causes, including Barrett's esophagus, mediastinal irradiation, oral medications, metastatic tumor or, rarely, dermatologic diseases such as epidermolysis bullosa dystrophica and benign mucous membrane pemphigoid. When a lye stricture has irregular margins or relatively abrupt borders, differentiation from an infiltrating carcinoma may also be difficult. The ability to distinguish benign from malignant lesions

is particularly important because of the increased risk of developing esophageal carcinoma in long-standing lye strictures (Fig. 21-12).^{57,58} Thus, endoscopy and biopsy may be required for a definitive diagnosis.

Idiopathic Eosinophilic Esophagitis

Since its original description by Attwood and associates in 1993,⁶⁴ eosinophilic esophagitis has been recognized as a chronic inflammatory disorder in children and adults.⁶⁵⁻⁶⁷ Eosinophilic esophagitis has been diagnosed with greater frequency over the past 2 decades, probably because of increasing awareness and increasing prevalence of this condition.⁶⁸ The diagnosis is established on pathologic grounds by an increased number of intraepithelial eosinophils (more than 20/high-power field) on endoscopic biopsy specimens from the esophagus.^{64,67} The cause is uncertain, but investigators believe that this condition develops as a result of an allergic immune response to ingested food items involving T-cell mediated hypersensitivity and immunoglobulin E (IgE)-mediated pathways, leading to eosinophilic activation, inflammation, and fibrosis.⁶⁹ Most patients with eosinophilic esophagitis do not have eosinophilic infiltration of the stomach and small bowel (eosinophilic gastroenteritis).

Figure 21-11 Advanced lye strictures. A, B. There is diffuse narrowing of the thoracic esophagus caused by extensive scarring and fibrosis in two patients with lye strictures. This appearance should suggest caustic injury because other conditions are rarely associated with such severe esophageal narrowing. (A from Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 21-12 Esophageal carcinoma arising in a lye stricture. There is a long stricture in the thoracic esophagus caused by caustic ingestion many years earlier. The irregular appearance and abrupt proximal border (arrow) of the narrowed segment are caused by a superimposed carcinoma.

CLINICAL FINDINGS

Adults with eosinophilic esophagitis are typically young men who present with long-standing dysphagia and recurrent food impactions.⁶⁵⁻⁶⁷ These individuals may have an atopic history (e.g., asthma, allergic rhinitis, and other allergic conditions) and peripheral eosinophilia,⁷⁰ but eosinophilic esophagitis often occurs as an isolated condition in the absence of an allergic history or peripheral eosinophilia.^{67,71}

Based on the assumption that food allergens act as antigenic stimulation for eosinophilic inflammation of the esophagus, most patients are treated with antiallergy therapy, including oral steroids, topical steroids (swallowing metered doses of aerosolized steroid preparations), and elemental diets (i.e., protein-free diets) or elimination food diets (diets that exclude food items most commonly associated with food allergies), with varying degrees of success.⁷²⁻⁷⁵ Patients with strictures causing intractable dysphagia may undergo endoscopic dilation procedures, but these individuals often have only transient relief of dysphagia, so multiple dilations may be required.^{67,76}

RADIOGRAPHIC FINDINGS

Eosinophilic esophagitis may be manifested on esophagography by strictures, rings, diffuse esophageal narrowing, or some

combination of these findings. Not infrequently, affected patients develop one or more segmental strictures in the upper or midesophagus or, less commonly, distal esophagus.^{70,77-79} These strictures typically appear as relatively long segments of concentric narrowing with smooth contours and tapered margins, although strictures in the distal esophagus tend to be shorter than those in the upper or midesophagus (Fig. 21-13A).⁷⁹ Other patients may develop a so-called ringed esophagus, manifested on barium studies by distinctive ringlike indentations, with multiple closely spaced concentric rings traversing the lumen (see Fig. 21-13A).⁸⁰ The rings may be associated with strictures or a small-caliber esophagus (see later) or may occur as an isolated finding in the esophagus.^{79,80} Although the pathogenesis is uncertain, such rings have been well documented at endoscopy, producing a typical corrugated appearance.⁸¹⁻⁸³ Still other patients with eosinophilic esophagitis may have diffuse loss of caliber of most or all of the thoracic esophagus, resulting in a so-called small-caliber esophagus (Fig. 21-13B).⁷⁹ Paradoxically, these long segments of narrowing can be more difficult to recognize on barium studies than shorter segments of narrowing because of their long length, uniform luminal diameter, and smooth contour, without obvious demarcations from adjacent normal-caliber esophagus. Despite the frequent subtlety of this finding, eosinophilic esophagitis should be suspected when a small-caliber esophagus is detected on barium

Figure 21-13 Eosinophilic esophagitis.

A. A mild area of tapered narrowing is seen in the midesophagus, with several distinctive ringlike indentations (*white arrows*) in the region of the stricture, producing a ringed esophagus. Note a second short stricture (*black arrow*) in the distal esophagus. **B.** In another patient, there is diffuse loss of distensibility of the entire thoracic esophagus, producing a small-caliber esophagus. The ringed esophagus and small-caliber esophagus are both characteristic of eosinophilic esophagitis.

studies in the proper clinical setting. In symptomatic patients, treatment with topical steroids can lead to improved esophageal diameter and relief of solid-food dysphagia.⁸⁴ It is therefore unclear whether the small-caliber esophagus results from actual fibrosis and stricture formation or other pathophysiologic mechanisms.

Other patients with eosinophilic esophagitis may have abnormal esophageal motility, with an increased frequency of nonperistaltic contractions or even an achalasia-like syndrome.^{77,85} Rarely, small, sessile eosinophilic polyps may be found in the esophagus.^{77,78}

DIFFERENTIAL DIAGNOSIS

Upper or midesophageal strictures in eosinophilic esophagitis cannot always be differentiated from high esophageal strictures caused by Barrett's esophagus, mediastinal irradiation, caustic ingestion, and metastatic tumor. The presence of an atopic history or peripheral eosinophilia, however, should suggest the correct diagnosis. In contrast, distal esophageal strictures in eosinophilic esophagitis may be impossible to differentiate from peptic strictures. Rarely, a long esophageal stricture or even a small-caliber esophagus may develop in patients with lichen planus involving the esophagus.⁸⁶

A ringed esophagus has also been described in patients with congenital esophageal stenosis. These patients may have corrugated esophageal strictures with multiple concentric rings indistinguishable from those in eosinophilic esophagitis.⁸⁷ Although congenital esophageal stenosis is usually not associated with an allergic history or peripheral eosinophilia, this condition also occurs in young men with long-standing

dysphagia, and biopsy specimens from the esophagus may also reveal increased numbers of intraepithelial eosinophils.⁸⁷ Because of the similarities in the clinical, radiographic, and pathologic findings of these conditions, some of the reported patients with congenital esophageal stenosis may have had unrecognized eosinophilic esophagitis as the cause of their symptoms.

The differential diagnosis of the ringed esophagus includes fixed transverse folds in patients with strictures, but these folds generally are incomplete and further apart, producing a characteristic stepladder appearance.⁸⁸ The feline esophagus could also conceivably be mistaken for the ringed esophagus of eosinophilic esophagitis, but these transverse striations occur as a transient phenomenon and are not associated with strictures.

Crohn's Disease

The esophagus is the least common site of involvement by Crohn's disease in the GI tract. When the esophagus is involved, these patients almost always have associated disease in the small bowel or colon. As a result, esophageal lesions are usually found after a clinical diagnosis of Crohn's disease has been established. Occasionally, however, the onset of esophageal Crohn's disease coincides with the onset of disease in the small bowel or colon, so these patients do not necessarily have known Crohn's disease when they seek medical attention. Rarely, isolated esophageal Crohn's disease may occur before the development of disease elsewhere in the GI tract.⁸⁹

A definitive diagnosis of esophageal Crohn's disease requires histologic confirmation, but endoscopic biopsy specimens often

fail to reveal granulomas because of the superficial nature of the biopsies and patchy distribution of the disease.⁹⁰ As a result, the absence of definitive histologic findings should not preclude a diagnosis of Crohn's disease if the clinical and radiographic findings suggest this condition.

CLINICAL FINDINGS

Most patients with esophageal Crohn's disease have advanced Crohn's disease in the lower GI tract, so the clinical presentation is dominated by their ileocolitis. Nevertheless, esophageal Crohn's disease may cause dysphagia or, less commonly, odynophagia or upper GI bleeding.⁹⁰⁻⁹² Because the esophagus is rarely involved by Crohn's disease as an isolated finding, the diagnosis should be considered only in patients with known Crohn's disease elsewhere in the GI tract who develop dysphagia or other esophageal symptoms. When esophageal Crohn's disease is present, the clinical course may parallel that of the patient's ileal or colonic disease, with remission of upper and lower GI symptoms after medical or surgical treatment.⁹¹

RADIOGRAPHIC FINDINGS

Although Crohn's disease primarily affects the small bowel or colon, esophageal involvement has been recognized with increased frequency on double-contrast esophagography. The major advantage of double-contrast technique is its ability to detect aphthoid ulcers, which are seen on double-contrast examinations in about 3% of patients with Crohn's disease in the small bowel or colon.⁹² As in other portions of the GI tract, the aphthoid ulcers appear as punctate, slitlike, or ringlike collections of barium surrounded by radiolucent halos of edematous mucosa (Fig. 21-14).⁹²⁻⁹⁴ These ulcers are usually few in number and are sporadically distributed throughout the esophagus with intervening normal mucosa (see Fig. 21-14A), but may occasionally be more numerous (see Fig. 21-14B).⁹⁴

As the disease progresses, barium studies may reveal more severe esophagitis characterized by larger areas of ulceration, thickened folds, pseudomembranes, or even a cobblestone appearance.^{91,95} Other patients may develop transverse or longitudinal intramural tracks (Fig. 21-15) or tracheoesophageal, esophagobronchial, esophagomediastinal, or esophagogastric fistulas.^{91,95} Progressive scarring may also lead to the development of strictures, usually in the distal esophagus (Fig. 21-16).⁹¹ Rarely, advanced esophageal Crohn's disease may be manifested by filiform polyposis of the esophagus, analogous to filiform polyposis of the colon in granulomatous colitis.⁹⁶

DIFFERENTIAL DIAGNOSIS

The aphthoid ulcers of esophageal Crohn's disease may be indistinguishable from discrete superficial ulcers associated with reflux, herpes, or drug-induced esophagitis. However, reflux esophagitis predominantly involves the distal esophagus and usually occurs in patients with reflux symptoms. Although herpetic ulcers may closely resemble aphthoid ulcers,³⁵ the correct diagnosis should be apparent in an immunocompromised patient with odynophagia. Drug-induced esophagitis may also be manifested by shallow ulcers, but they tend to be

Figure 21-14 Esophageal Crohn's disease with aphthoid ulcers.

A. Discrete, widely separated aphthoid ulcers are seen en face (straight arrow) and in profile (curved arrow) as a result of early esophageal involvement by Crohn's disease. **B.** This patient has more advanced Crohn's disease, with multiple large aphthoid ulcers in the midesophagus and distal esophagus. The ulcers are surrounded by radiolucent mounds of edema. (**A** from Gohel V, Long BW, Richter G: Aphthous ulcers in the esophagus with Crohn colitis. *AJR* 137:872-873, 1981; **B** courtesy Peter J. Feczko, MD, Royal Oak, MI.)

clustered in the midesophagus near the aortic arch or left main bronchus, and there is usually a recent history of ingesting oral medications such as tetracycline or doxycycline.³¹⁻³³ Thus, the clinical history and presentation are extremely helpful for differentiating these conditions.

More advanced esophageal Crohn's disease may be indistinguishable from other types of severe esophagitis. When intramural tracks or fistulas are present, the differential diagnosis includes radiation, trauma, malignant tumor, tuberculosis, and esophageal intramural pseudodiverticulosis.⁹⁷⁻⁹⁹ Because esophageal Crohn's disease is much less common than other types of esophagitis, this diagnosis should be considered only in patients who have clinical or radiographic findings of Crohn's disease elsewhere in the GI tract.

Epidermolysis Bullosa Dystrophica

Epidermolysis bullosa is a rare hereditary skin disease in which minimal trauma causes separation of the epidermis and dermis, with subsequent bulla formation. Two forms of the disease,

Figure 21-15 Esophageal Crohn's disease with intramural tracks. **A.** Longitudinal (long arrows) and transverse (short arrow) tracks are seen in the distal third of the esophagus because of transmural involvement by Crohn's disease. **B.** This patient has a so-called double-barreled esophagus with a long intramural track as a result of advanced esophageal Crohn's disease. (**A** courtesy Peter J. Feczko, MD, Royal Oak, MI; **B** courtesy Francis J. Scholz, MD, Burlington, MA.)

Figure 21-16 Esophageal Crohn's disease with strictures. **A, B.** Two patients have long strictures in the distal esophagus as a result of severe scarring from Crohn's disease. (**A** from Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989; **B** from Tishler JMA, Hellman CA: *Crohn's disease of the esophagus*. *Can Assoc Radiol J* 35:28–30, 1984.)

epidermolysis bullosa simplex and epidermolysis bullosa dystrophica, have been described. In epidermolysis bullosa simplex, the bullae heal without scarring, and the disease usually subsides at puberty. In contrast, epidermolysis bullosa dystrophica is a mutilating, potentially lethal condition manifested by progressive scarring and deformity throughout the body.¹⁰⁰ Epidermolysis bullosa dystrophica may be transmitted by autosomal dominant and autosomal recessive forms of inheritance. The autosomal dominant form involves only the skin, whereas the autosomal recessive form also involves mucous membranes in other squamous epithelium-lined organs such as the oropharynx, esophagus, and anus.¹⁰⁰

PATHOGENESIS

In patients with epidermolysis bullosa dystrophica, solid food in the esophagus repeatedly traumatizes an already fragile mucosa, causing extensive bulla formation.^{100,101} Some bullae rupture and heal without permanent sequelae, but others heal with severe scarring and stricture formation. Because these strictures further impede the passage of swallowed food, esophageal involvement may lead to a self-perpetuating cycle of blistering, scarring, and stenosis.¹⁰¹

CLINICAL FINDINGS

Skin involvement by epidermolysis bullosa dystrophica may be recognized at or shortly after birth. Other findings include flexion contractures of the hands and feet, webbed digits (syndactyly), dystrophic or absent nails, microstomia, retarded epiphyseal development, and overconstriction of long bones.¹⁰² These deformities can be disabling or even fatal.

Although the esophagus is usually affected during the first decade of life, clinical signs of esophageal involvement may not be seen until puberty.¹⁰³ Affected individuals may present with intermittent dysphagia or odynophagia because of recurrent bulla formation and healing.^{103,104} Subsequently, they may develop severe dysphagia as a result of irreversible scarring and stricture formation.^{101,103,104} Esophageal involvement should therefore be suspected in any patient with epidermolysis bullosa dystrophica who develops dysphagia or other esophageal symptoms.

Endoscopy should be avoided in patients with known or suspected epidermolysis bullosa dystrophica involving the esophagus because of the risk of further traumatizing an already fragile mucosa and causing bleeding, perforation, or further scarring and stenosis. Once strictures have developed, however,

balloon dilation or bougienage of the esophagus or, rarely, surgery may be required to alleviate symptoms.^{100,104}

RADIOGRAPHIC FINDINGS

Because of the risks associated with endoscopy, barium studies should be performed when esophageal involvement by epidermolysis bullosa dystrophica is suspected on clinical grounds. Early disease may be manifested by abnormal motility, bullae, or ulcers.^{103,105} Discrete bullae may be recognized as small, nodular filling defects in the esophagus, whereas extensive bulla formation may produce a diffusely serrated or spiculated esophageal contour.¹⁰³ Because of the reversible nature of the disease, these lesions may completely regress on follow-up examinations.

More advanced esophageal disease is characterized by scarring and stricture formation. The strictures tend to be located in the cervical or upper thoracic esophagus, appearing as concentric areas of segmental narrowing (Fig. 21-17).^{103,105-107} These strictures may be difficult to differentiate from those caused by Barrett's esophagus, mediastinal irradiation, and caustic ingestion. Other patients with epidermolysis bullosa dystrophica may develop esophageal webs, usually in the cervical esophagus near the cricopharyngeus.^{103,106} Esophageal involvement by epidermolysis bullosa dystrophica should be suspected when high esophageal strictures or webs are seen on barium

Figure 21-17 Epidermolysis bullosa dystrophica with a high esophageal stricture (arrow). (From Tishler JM, Han SY, Hellman CA: Esophageal involvement in epidermolysis bullosa dystrophica. *AJR* 141:1283-1286, 1983.)

studies in children or young adults with other clinical signs of this disease.

Pemphigoid

Pemphigoid is a dermatologic disease characterized by chronic, recurrent bullous eruptions of the skin and mucous membranes. Two forms of pemphigoid, benign mucous membrane pemphigoid and bullous pemphigoid, have been described. Benign mucous membrane pemphigoid is much more likely to involve mucous membranes, however, so esophageal abnormalities are primarily encountered in this form of the disease.

CLINICAL FINDINGS

Benign mucous membrane pemphigoid usually occurs in middle-aged patients and is twice as common in women.¹⁰⁸ About 75% of patients have involvement of the oral mucosa and conjunctiva, 50% have skin involvement, and 5% to 10% have esophageal involvement.¹⁰⁸⁻¹¹⁰ The most severe complications of this disease occur in the eye, in which conjunctival scarring causes corneal destruction and blindness in 25% of patients.¹⁰⁹ Thus, despite its name, benign mucous membrane pemphigoid should not be considered a benign condition.

Affected individuals usually present with dysphagia caused by edema, spasm, ulceration, or strictures.^{108,110} Severe esophageal involvement may occasionally result in massive sloughing of mucosa, with subsequent expulsion of a hollow membranous cast from the patient's mouth.¹¹¹ When these patients initially develop dysphagia, systemic administration of steroids may prevent further progression of esophageal disease and stricture formation. Once strictures have developed, however, one or more esophageal dilation procedures are usually required to alleviate symptoms.¹¹²

RADIOGRAPHIC FINDINGS

Although discrete bullae are rarely observed, barium studies may reveal superficial ulceration in the early stages of esophageal involvement by benign mucous membrane pemphigoid (Fig. 21-18).¹⁰⁸ Subsequent scarring may lead to the development of webs or strictures in the cervical or upper thoracic esophagus (Fig. 21-19) or, less commonly, the mid or lower thoracic esophagus.^{108,110,113,114} The strictures are of variable length and may be difficult to distinguish from those caused by Barrett's esophagus, mediastinal irradiation, and caustic ingestion. However, esophageal involvement by benign mucous membrane pemphigoid should be suspected in patients who have a history of bullous eruptions on the skin.

Erythema Multiforme Major

CLINICAL FINDINGS

Erythema multiforme is a hypersensitivity reaction characterized by a maculopapular or bullous rash that usually develops during the first 3 decades of life.¹¹⁵ Erythema multiforme minor is confined to the skin, but erythema multiforme major also involves mucous membranes of the eyes, oropharynx, genitalia, or anus and, rarely, the tracheobronchial tree or esophagus.¹¹⁵ Stevens-Johnson syndrome is a life-threatening form of

Figure 21-18 Benign mucous membrane pemphigoid with superficial ulceration. Multiple shallow ulcers (arrows) are seen in the midesophagus, with decreased distensibility of this region. (Courtesy Stephen E. Rubesin, MD, Philadelphia.)

Figure 21-19 Benign mucous membrane pemphigoid with a high esophageal stricture. A long asymmetric stricture is seen in the cervical and upper thoracic esophagus. (Courtesy John A. Bonavita, MD, Philadelphia.)

esophageal multiforme major, with associated constitutional symptoms.¹¹⁶

RADIOGRAPHIC FINDINGS

Esophageal involvement by erythema multiforme major is usually self-limited, but occasional children or adolescents have been reported with dysphagia caused by esophageal strictures, predominantly in the upper or midesophagus.¹¹⁶⁻¹¹⁸ Rarely, barium studies may reveal diffuse esophageal narrowing in children or adults with this condition.¹¹⁹ Other more common causes of long esophageal strictures include mediastinal irradiation and caustic ingestion, but esophageal involvement by erythema multiforme major should be suspected in patients with characteristic mucocutaneous lesions. Epidermolysis bullosa dystrophica and benign mucous membrane pemphigoid may also be associated with bullous lesions on the skin and esophageal strictures, but these patients usually have focal strictures or webs in the cervical or upper thoracic esophagus (see earlier, “Epidermolysis Bullosa Dystrophica” and “Pemphigoid”).

Nasogastric Intubation Esophagitis

Nasogastric intubation has been recognized as an unusual cause of esophagitis and strictures.^{120,121} Most patients develop strictures only after repeated or prolonged nasogastric intubation. These strictures may progress rapidly after removal of the tube,

causing severe dysphagia. When all causes of esophageal strictures are considered, nasogastric intubation is probably second only to caustic ingestion in terms of the length and severity of stricture formation.

PATHOGENESIS

The pathogenesis of esophageal injury is uncertain. Most patients who develop strictures have been intubated for 3 to 15 days.¹²¹ Some investigators believe that esophagitis results from uncontrolled gastroesophageal reflux around the lower end of the nasogastric tube, whereas others think that the tube occludes the lower esophageal sphincter, preventing clearance of refluxed acid from the esophagus.¹²² It has also been postulated that the irritant effect of the tube itself may cause a direct contact esophagitis.¹²³

CLINICAL FINDINGS

Most patients with esophageal injury develop symptoms several weeks to months after removal of the nasogastric tube.^{120,121} They may initially present with heartburn, chest pain, or odynophagia from severe esophagitis. Subsequently, they may develop progressive dysphagia as a result of rapid stricture formation.¹²¹ Despite the length and severity of the strictures, adequate relief from dysphagia may be obtained by periodic dilation procedures.

RADIOGRAPHIC FINDINGS

Nasogastric intubation esophagitis may be manifested by a long segment of extensive ulceration in the distal esophagus (Fig. 21-20).¹²³ Occasionally, large flat ulcers are associated with considerable mass effect because of an adjacent mound of edema, mimicking the appearance of an ulcerated esophageal carcinoma (Fig. 21-21). Subsequent stricture formation may be detected on esophagography 1 to 4 months after removal of the tube.^{120,121} Initially, the strictures may appear as smooth, tapered areas of concentric narrowing in the distal esophagus that are indistinguishable from ordinary peptic strictures. However, they tend to progress rapidly, increasing in length and severity within a relatively short period (Fig. 21-22). Because of the extent and severity of stricture formation, these patients may be suspected of ingesting caustic agents. However, nasogastric intubation strictures always involve the distal esophagus, so the presence of an unusually long or rapidly progressive stricture in the distal esophagus should suggest the correct diagnosis.

Alkaline Reflux Esophagitis

Alkaline reflux esophagitis is an unusual condition caused by reflux of bile and pancreatic secretions into the esophagus

after total or, less commonly, partial gastrectomy.¹²⁴ The development of esophagitis in these patients depends on the type of surgical reconstruction that is used. Alkaline reflux esophagitis is a common complication of total gastrectomy and simple loop esophagojejunostomy but rarely occurs after Roux-en-Y esophagojejunostomy.^{125,126} Most surgeons therefore perform a Roux-en-Y reconstruction, placing the jejunoejunal anastomosis 40 cm or more distal to the esophagojejunal anastomosis to prevent reflux of bile into the esophagus. Nevertheless, alkaline reflux esophagitis has occasionally been documented in these patients, so a Roux-en-Y reconstruction decreases the risk of esophagitis and stricture formation but does not completely eliminate these complications.¹²⁷ Some investigators have found that alkaline reflux esophagitis also predisposes to the development of Barrett's esophagus.^{128,129}

CLINICAL FINDINGS

Alkaline reflux esophagitis may initially be manifested by retrosternal burning, chest pain, and regurgitation of bile.¹²⁵ These patients may then develop worsening dysphagia within several months after surgery because of rapidly progressive stricture formation. In most cases, relief from dysphagia is obtained by mechanical dilation of the stricture.

Figure 21-20 Severe esophagitis caused by nasogastric intubation. There are multiple areas of superficial ulceration and associated narrowing of the distal esophagus caused by marked edema and spasm. A large hiatal hernia is also present. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 21-21 Giant esophageal ulcer caused by nasogastric intubation. A large, flat ulcer (white arrows) is seen in the distal esophagus; an associated area of mass effect (black arrows) is caused by an adjacent mound of edema. This appearance could be mistaken for that of an ulcerated esophageal carcinoma. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 21-22 Rapidly progressive stricture caused by nasogastric intubation. **A.** Initial esophagogram shows moderately decreased distensibility of the distal esophagus shortly after removal of a nasogastric tube. **B.** Second esophagogram 3 weeks later shows rapid stricture formation with marked narrowing of the distal esophagus. **C.** Third esophagogram 6 weeks later shows further progression of the stricture. There is now evidence of esophageal obstruction. (Courtesy Vijay Gohel, MD, Philadelphia.)

RADIOGRAPHIC FINDINGS

Alkaline reflux esophagitis is characterized on esophagography by mucosal nodularity, thickened folds, and ulceration of the distal esophagus above the esophagojejunal anastomosis (Fig. 21-23).¹³⁰ Subsequent stricture formation may be detected as early as 1 to 3 months after surgery.¹³⁰ The strictures usually appear as smooth tapered areas of narrowing, often extending a considerable distance above the anastomosis.¹³⁰ These strictures must be differentiated from benign anastomotic strictures or recurrent tumor involving the distal esophagus. However, anastomotic strictures usually appear as focal areas of symmetric narrowing at the esophagojejunal anastomosis, whereas recurrent tumor is manifested by more irregular esophageal narrowing and an eccentric mass effect.¹³⁰ Because patients who undergo total or partial gastrectomy are usually intubated at the time of surgery, nasogastric intubation should be considered as another cause of rapidly developing strictures in these individuals.

Acute Alcohol-Induced Esophagitis

Alcohol abusers may occasionally develop an acute, transient esophagitis after an alcoholic binge.¹³¹ The cause is uncertain, but heavy alcohol consumption appears to have an effect on esophageal peristalsis and lower esophageal sphincter function. Several studies have shown that oral or intravenous ethanol in volunteers produces a reversible esophageal motor disturbance characterized by impaired primary peristalsis and decreased lower esophageal sphincter pressures.^{132,133} As a result, acute alcohol intoxication may promote gastroesophageal reflux with impaired clearance of refluxed peptic acid from the esophagus after reflux has occurred. Thus, alcohol-induced

Figure 21-23 Alkaline reflux esophagitis. This patient has undergone a total gastrectomy and esophagojejunostomy. A nodular mucosa is seen in the distal esophagus above the anastomosis. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 21-24 Acute alcohol-induced esophagitis. A, B. In both patients, multiple small, superficial ulcers are present in the midesophagus and distal esophagus. Reflux esophagitis could produce identical findings, but esophageal symptoms were precipitated by a recent alcoholic binge in both cases. (From O'Riordan D, Levine MS, Laufer I: *Acute alcoholic esophagitis*. *Can Assoc Radiol J* 37:54–55, 1986.)

esophagitis most likely represents a self-limited form of reflux esophagitis.

CLINICAL FINDINGS

Acute alcohol-induced esophagitis may be associated with abrupt onset of odynophagia, dysphagia, or hematemesis immediately after an alcoholic binge.¹³¹ Marked clinical improvement occurs within 1 to 2 weeks after withdrawal of alcohol.¹³¹ Although other conditions may have a similar presentation, the correct diagnosis is usually suggested by the temporal relationship between an alcoholic binge and the development of esophagitis.

RADIOGRAPHIC FINDINGS

Acute alcohol-induced esophagitis is manifested radiographically by multiple areas of superficial ulceration in the distal third of the esophagus (Fig. 21-24).¹³¹ Reflux esophagitis may produce identical radiographic findings. Nevertheless, the diagnosis should be suggested by the patient's recent drinking history.

Chronic Graft-Versus-Host Disease

Transplantation of bone marrow from matched sibling donors has become an accepted treatment for patients with aplastic anemia, acute leukemia, and other hematologic malignancies. Depending on the underlying disease, these patients have 5-year survival rates of 60% to 80% after marrow transplantation.¹³⁴ However, 30% of long-term survivors develop chronic graft-versus-host disease within 3 to 12 months after undergoing this procedure.¹³⁵ The disease is an immunologic disorder in which immunocompetent donor lymphocytes react against antigenic differences in host tissues, causing severe tissue damage. The most frequently involved target organs are the skin and liver, but the eyes, mucous membranes, and GI tract may also be affected.¹³⁴⁻¹³⁶

Esophageal involvement occurs in about 15% of patients with chronic graft-versus-host disease.¹³⁷ The immunologic process causes bulla formation, followed by desquamation and sloughing of the esophageal mucosa and subsequent stricture formation.¹³⁷⁻¹³⁹ The pathologic findings appear to be similar to those of epidermolysis bullosa dystrophica, benign mucous membrane pemphigoid, and other diseases associated with severe scarring and stricture formation in the esophagus.

CLINICAL FINDINGS

Symptoms of esophageal involvement by chronic graft-versus-host disease include dysphagia, odynophagia, substernal chest pain, and weight loss.^{135,137} Infectious esophagitis may produce similar findings in this clinical setting,¹⁴⁰ but opportunistic infection of the esophagus often develops within 1 to 8 weeks after marrow transplantation, whereas chronic graft-versus-host disease usually occurs later (3 to 12 months after transplantation).¹³⁷ The temporal relationship between marrow transplantation and the development of symptoms is therefore helpful for differentiating these conditions.

RADIOGRAPHIC FINDINGS

In early esophageal involvement by chronic graft-versus-host disease, the esophagus may have an irregular, serrated contour secondary to mucosal desquamation and sloughing.¹³⁷ With the development of scarring, barium studies may reveal webs or strictures in the esophagus. Webs are usually found in the cervical esophagus near the level of the cricopharynx (Fig. 21-25A).¹³⁷ These lesions cannot be differentiated from idiopathic webs or those associated with other conditions such as epidermolysis bullosa dystrophica and benign mucous membrane pemphigoid. Other patients may develop ringlike or smoothly tapered strictures in the upper, mid, or, less commonly, distal esophagus (Fig. 21-25B).^{135,137} The correct diagnosis should be suggested in patients who are known to have undergone marrow transplantation.

Glutaraldehyde-Induced Esophageal Injury

Glutaraldehyde is the agent most commonly used to disinfect endoscopic equipment. Outbreaks of hemorrhagic colitis in patients who underwent colonoscopy have been attributed to inadequate cleaning and rinsing of endoscopic equipment, with

Figure 21-25 Chronic graft-versus-host disease with esophageal involvement.

A. A web is seen en face (arrow) in the cervical esophagus. **B.** A long tapered stricture is present in the distal esophagus in another patient. Nodular and linear filling defects (arrows) within the narrowed segment are caused by mucosal desquamation and sloughing. (**A** from McDonald GB, Sullivan KM, Plumley TF: Radiographic features of esophageal involvement in chronic graft-vs.-host disease. *AJR* 142:501–506, 1984; **B** courtesy Seth N. Glick, MD, Philadelphia.)

subsequent exposure of the colonic mucosa to residual glutaraldehyde.¹⁴¹ A study on laboratory rats has shown that glutaraldehyde also has a toxic effect on the esophagus, causing inflammation and segmental vasculitis.¹⁴² Rarely, esophageal strictures may develop in humans within several weeks of endoscopy, presumably because of exposure to glutaraldehyde-contaminated endoscopic equipment (Fig. 21-26).¹⁴² Exposure to glutaraldehyde should therefore be considered as a possible cause of esophagitis and rapidly progressive esophageal strictures in these patients.

Behçet's Disease

Behçet's disease was first described by Behçet in 1937 as the clinical triad of oral and genital ulceration and ocular inflammation. Behçet's disease is now recognized as a multisystem disorder characterized by a nonspecific vasculitis with resulting skin lesions, arthritis, colitis, thrombophlebitis, and, rarely, encephalitis.^{143,144} In the GI tract, Behçet's disease usually involves the colon, producing a localized or diffuse form of colitis in about 20% of patients.¹⁴³ Esophageal involvement has occasionally been reported.¹⁴⁴⁻¹⁴⁹ Affected individuals may present with substernal chest pain, dysphagia, and hematemesis.^{144,145} Double-contrast esophagography may reveal discrete superficial ulcers in the midesophagus (Fig. 21-27), widespread esophagitis, or strictures.¹⁴⁴ Rarely, a single giant ulcer may be observed.¹⁴⁶ Because Behçet's disease is often treated with steroids or other immunosuppressive agents, herpes esophagitis should be suspected as a more likely cause of esophageal ulcers in these patients. Endoscopic brushings, biopsy specimens, and cultures are therefore required to differentiate this condition from viral esophagitis.

Esophageal Intramural Pseudodiverticulosis

When esophageal intramural pseudodiverticulosis was first described in 1960, it was thought that mucosal herniation through defects in the esophageal wall produced true intramural diverticula, analogous to Rokitansky-Aschoff sinuses in the gallbladder.¹⁵⁰ Since that time, however, the pathologic basis for these structures has been well elucidated. Although esophageal intramural pseudodiverticulosis is a relatively uncommon condition, it has received considerable attention in the radiologic literature because of its often spectacular appearance on barium studies.

PATHOGENESIS

The esophagus normally contains about 200 deep mucous glands that occur in longitudinal rows parallel to the long axis of the esophagus.¹⁵¹ Within each gland, several short ducts converge to form a single main excretory duct that extends 2 to 5 mm through the esophageal wall, producing a small opening on the mucosa.¹⁵² Pathologic studies have shown that esophageal intramural pseudodiverticula represent dilated excretory ducts of these deep mucous glands.¹⁵³⁻¹⁵⁵

Although the anatomic basis of these structures has been well delineated, the explanation for this ductal dilation is unclear. One organism, *Candida albicans*, has been cultured from the esophagus in 34% to 50% of patients.^{151,156-158} It has therefore been postulated that *Candida* esophagitis predisposes to the development of esophageal intramural pseudodiverticulosis.¹⁵⁹ However, most investigators instead believe that the fungal organisms are secondary esophageal invaders and are not

Figure 21-26 Glutaraldehyde-induced esophageal stricture. A long, tapered stricture is seen in the thoracic esophagus. This stricture developed 1 month after endoscopy, presumably because of exposure to residual glutaraldehyde on the endoscopic equipment. Scarring from caustic ingestion could produce identical radiographic findings.

important causative factors in the development of this condition.^{154,160-162}

Others have postulated that ductal dilation results from plugging and obstruction of the ducts by thick, viscous mucus and inflammatory material.¹⁵²⁻¹⁵⁴ In various series, 80% to 90% of patients with pseudodiverticulosis have had endoscopic or histologic evidence of inflammatory disease in the esophagus.^{151,157} In one study, most patients also had scarring or strictures in the distal esophagus caused by reflux esophagitis.¹⁶³ Thus, esophageal intramural pseudodiverticulosis most likely occurs as a sequela of chronic esophagitis, particularly reflux esophagitis, but it is unclear why so few patients with esophagitis develop this condition.

About 90% of patients with esophageal intramural pseudodiverticulosis have associated strictures.^{151,156,157} It has therefore been suggested that increased intraluminal pressure or stasis above the stricture may cause ductal dilation.¹⁵² This theory is weakened, however, by the observation that the pseudodiverticula are often found below the level of the stricture.¹⁵¹ Conversely, stricture formation could be caused by the development of microabscesses in the ducts, resulting in perforation, peridiverticulitis, and scarring.^{162,164} This hypothesis would explain why there is often no other apparent cause for the development of esophageal strictures in these patients.

Figure 21-27 Behçet's disease with superficial ulceration. A cluster of tiny ulcers (arrows) is present in the midesophagus. Herpes esophagitis and drug-induced esophagitis are much more common causes of discrete ulcers in the midesophagus. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

CLINICAL FINDINGS

Esophageal intramural pseudodiverticulosis usually occurs in older adults and is slightly more common in men.^{151,156-158} About 20% of patients are diabetics, and 15% are alcoholics.^{143,144} Most patients present with intermittent or slowly progressive dysphagia resulting from the high prevalence of associated strictures.^{151,153,156,157,161,162}

Treatment is usually directed toward the underlying stricture because the pseudodiverticula themselves rarely cause symptoms. Dilation of strictures produces a marked clinical response in almost all patients.^{162,164} The pseudodiverticula may persist or disappear after treatment, but the fate of these structures has no relationship to the clinical course of the patient.

RADIOGRAPHIC FINDINGS

Esophageal intramural pseudodiverticulosis is diagnosed in fewer than 1% of all patients who undergo barium esophagograms.¹⁶³ Failure to visualize the pseudodiverticula may result from ductal obstruction by inflammatory material or debris that prevents barium from entering the ducts. Nevertheless, esophagography is more sensitive than endoscopy for detecting these lesions because the orifices of the

Figure 21-28 Esophageal intramural pseudodiverticulosis with high strictures. A, B. In both cases, the pseudodiverticula appear as characteristic outpouchings in longitudinal rows parallel to the long axis of the esophagus. Associated strictures (arrows) are seen in the upper thoracic esophagus. (**B** from Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

dilated excretory ducts are extremely difficult to visualize at endoscopy.¹⁵⁶

Esophageal intramural pseudodiverticulosis is classically manifested by innumerable, tiny (1- to 4-mm), flask-shaped outpouchings in longitudinal rows parallel to the long axis of the esophagus (Fig. 21-28).^{151,153,156,157,160,164}

Because the necks of the pseudodiverticula are 1 mm or less in diameter, incomplete filling may erroneously suggest lack of communication with the esophageal lumen.¹⁶³ The pseudodiverticula may occasionally be recognized on CT by thickening of the esophageal wall, irregularity of the lumen, and intramural gas collections within these structures.¹⁶⁵

Bridging may sometimes occur between adjacent pseudodiverticula, resulting in discrete intramural tracks (Fig. 21-29).^{156,157,160} In one study, intramural tracking was detected on esophagography in 50% of patients with esophageal intramural pseudodiverticulosis.⁹⁹ These tracks may vary from short, thin connections between two or more pseudodiverticula to long intramural collections of barium paralleling the lumen.⁹⁹ Occasionally, these long tracks can be mistaken for large ulcers or even extraluminal collections associated

Figure 21-29 Esophageal intramural pseudodiverticulosis with an intramural track. This track (arrow) is caused by bridging of adjacent pseudodiverticula. Other pseudodiverticula seen en face could be mistaken for shallow ulcers. (Courtesy Stephen E. Rubesin, MD, Philadelphia.)

with an intramural esophageal dissection or contained perforation.⁹⁹

Half of the reported patients with esophageal intramural pseudodiverticulosis have diffuse disease, and the remaining 50% have segmental disease.^{151,156,157} About 90% of patients have associated strictures, usually in the distal esophagus, with a focal cluster of pseudodiverticula in the region of a peptic stricture (Fig. 21-30).¹⁶³ Other patients may have segmental strictures in the upper or middle third of the esophagus (see Fig. 21-28).^{151,156,157} In such cases, the pseudodiverticula often extend well above and below the level of the stricture.¹⁵⁶ Although most patients with esophageal intramural pseudodiverticulosis have esophagitis or strictures, pseudodiverticula may occasionally be observed in patients with an otherwise normal-appearing esophagus.¹⁶³

Esophageal intramural pseudodiverticulosis has also been reported in patients with esophageal carcinoma.¹⁶⁶ Such cases could conceivably result from malignant degeneration of preexisting peptic strictures in patients with Barrett's esophagus. Whatever the explanation, strictures associated with pseudodiverticulosis are not always benign, so these strictures should be evaluated individually for radiographic signs of malignancy.

Figure 21-30 Esophageal intramural pseudodiverticulosis with a peptic stricture. When viewed en face, the pseudodiverticula could be mistaken for tiny ulcers. When viewed in profile, however, the pseudodiverticula (arrows) do not appear to communicate with the esophageal lumen. This characteristic feature helps differentiate these structures from ulcers. There also is narrowing and deformity of the distal esophagus caused by an associated peptic stricture. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Rarely, perforation of an esophageal intramural pseudodiverticulum may result in diverticulitis, with the development of a periesophageal inflammatory mass or abscess in the mediastinum.^{167,168} Affected individuals may present with chest pain, fever, leukocytosis, or other signs of mediastinitis.¹⁶⁸ In such cases, esophagography may reveal localized extravasation of contrast material into the mediastinum from the perforated pseudodiverticulum (Fig. 21-31).¹⁶⁸ CT may also reveal a periesophageal inflammatory mass with or without associated collections of gas.¹⁶⁷ In previously reported cases, the perforations have sealed off with parenteral nutrition and intravenous antibiotics.^{167,168} Thus, esophageal perforation caused by ruptured pseudodiverticula may be more likely to heal on conservative medical treatment than other types of esophageal perforations.

Figure 21-31 Esophageal intramural pseudodiverticulosis with associated diverticulitis. There is a large, irregular extraluminal barium collection (arrows), presumably caused by a sealed-off perforation of a pseudodiverticulum. (Courtesy Peter J. Feczko, MD, Royal Oak, MI.)

DIFFERENTIAL DIAGNOSIS

The radiographic findings of esophageal intramural pseudodiverticulosis are pathognomonic of this condition. Although pseudodiverticula can occasionally be confused with true diverticula, the latter structures are considerably larger and less numerous and should not pose a major diagnostic dilemma. When viewed en face, pseudodiverticula can also be mistaken for tiny ulcers associated with various types of esophagitis (see Fig. 21-30). When viewed in profile, however, the pseudodiverticula have a typical flask-shaped configuration and often seem to be floating outside the esophageal wall without any apparent communication with the lumen, whereas true ulcers almost always communicate directly with the lumen. The characteristic tangential appearance of the pseudodiverticula should therefore differentiate these structures from actual areas of ulceration.

Benign Tumors of the Esophagus

MARC S. LEVINE

CHAPTER OUTLINE

Mucosal Lesions

Papilloma
Adenoma
Inflammatory Esophagogastric Polyp
Glycogenic Acanthosis
Leukoplakia
Acanthosis Nigricans

Submucosal Lesions

Leiomyoma
Gastrointestinal Stromal Tumor
Leiomyomatosis and Idiopathic Muscular Hypertrophy
Fibrovascular Polyp
Granular Cell Tumor
Lipoma
Hemangioma
Hamartoma
Other Mesenchymal Tumors
Cysts

Benign tumors of the esophagus constitute only about 20% of all esophageal neoplasms.¹ Most are small lesions that cause no symptoms and are discovered fortuitously on barium studies or endoscopy. Occasionally, however, these tumors may cause dysphagia, bleeding, or other symptoms, necessitating endoscopic or surgical removal. Depending on their site of origin, benign esophageal neoplasms may be classified as mucosal or submucosal lesions, which have typical radiographic and endoscopic features.

Mucosal Lesions

PAPILLOMA

Squamous papillomas (or simply, papillomas) are uncommon benign tumors, accounting for less than 5% of all esophageal neoplasms.² The lesions consist histologically of a central fibrovascular core with multiple finger-like projections covered by hyperplastic squamous epithelium.³ Papillomas usually appear grossly as coral-like excrescences from the mucosa. Although the pathogenesis of these tumors is uncertain, the human papillomavirus⁴ and chronic reflux esophagitis⁵ have been implicated as causative factors.

All papillomas in the esophagus reported thus far have been benign lesions. Nevertheless, malignant degeneration has been observed in experimentally induced esophageal papillomas in rats.⁶ Malignant transformation has also been documented in papillomas arising in the oral cavity, larynx, and uterine cervix.⁷⁻⁹ In some cases, benign papillomas can be mistaken on histologic examination for verrucous carcinoma, an

uncommon form of squamous cell carcinoma.¹⁰ Thus, some investigators believe that all papillomas in the esophagus should be resected because of the uncertain risk of malignant degeneration and potential confusion with verrucous carcinoma.¹¹

Papillomas in the esophagus usually occur as solitary lesions, ranging from 0.5 to 1.5 cm in size. Most patients are asymptomatic, but dysphagia is an occasional finding.^{3,11} Rarely, multiple papillomas may be present in the esophagus, a condition known as *esophageal papillomatosis*.¹²⁻¹⁴

Radiographic Findings

Papillomas are difficult to detect on single-contrast barium studies because of the small size of the lesions. In contrast, they can be recognized on double-contrast studies as small (<1 cm), sessile polyps that have a smooth or slightly lobulated contour (Fig. 22-1).¹⁵ Because early esophageal cancers may also appear as small polypoid lesions, endoscopy should be performed to exclude an early carcinoma. Occasionally, larger papillomas may be manifested by lobulated intraluminal masses that are indistinguishable from advanced esophageal carcinoma. Rarely, esophageal papillomas may have a bubbly appearance secondary to trapping of barium between the papillary fronds of the tumor (Fig. 22-2).¹⁶

Multiple papillomas may be demonstrated on esophagography in patients with esophageal papillomatosis.¹²⁻¹⁴ Despite its rarity, the diagnosis of papillomatosis should be suggested by the presence of multiple, discrete, lobulated protrusions on the mucosa (Fig. 22-3). Even when multiple papillomas are present, these lesions rarely cause obstruction.

ADENOMA

Adenomas account for less than 1% of all benign esophageal neoplasms.¹⁷ They are rarely found in the esophagus because it is lined by squamous rather than columnar epithelium. However, adenomas may develop in patients with Barrett's esophagus (see Chapter 19).^{18,19} These adenomas are important because of the risk of malignant degeneration via an adenoma-carcinoma sequence similar to that found in the colon.^{18,19} Esophageal adenomas should therefore be resected endoscopically or surgically, whenever feasible.

Radiographic Findings

Esophageal adenomas may appear on barium studies as sessile or pedunculated polyps in the esophagus (Fig. 22-4). Larger, more lobulated lesions have a greater likelihood of harboring adenocarcinoma. Most adenomas are located in the distal esophagus at or near the gastroesophageal junction.¹⁷⁻¹⁹ As a result, they can be mistaken for inflammatory esophagogastric polyps (see next section). Nodularity, lobulation, and the large size of the lesion should favor an adenoma or adenocarcinoma. When an adenoma is suspected on barium studies, endoscopy and biopsy should be performed for a definitive diagnosis.

Figure 22-1 Papilloma. The lesion appears as a sessile, slightly lobulated polyp (arrows) in the midesophagus. An early esophageal carcinoma could produce similar findings.

Figure 22-2 Giant esophageal papilloma. The lesion has a bubbly appearance (arrows) caused by trapping of barium between the papillary fronds of the tumor. (From Walker JH: *Giant papilloma of the thoracic esophagus*. AJR 131:519–520, 1978.)

INFLAMMATORY ESOPHAGOGASTRIC POLYP

Although inflammatory esophagogastric polyps are not neoplastic, they are included in this chapter because they are characterized by the presence of a polypoid protuberance in the distal esophagus abutting the gastroesophageal junction. The polyp represents the bulbous tip of a thickened gastric fold extending into the distal esophagus from the gastric fundus.^{20–24} The lesions are composed of inflammatory and granulation tissue and are thought to be a sequela of chronic reflux esophagitis (see Chapter 19).^{21,22} Affected individuals may therefore have clinical signs of chronic reflux disease. Because inflammatory esophagogastric polyps have no malignant potential, endoscopic resection is unwarranted.²⁴

Radiographic Findings

Inflammatory esophagogastric polyps are usually manifested on barium studies by a single prominent fold that arises in the gastric fundus and extends into the distal esophagus as a smooth, ovoid, or club-shaped protuberance (Fig. 22-5A).^{20,23,24} The lesions frequently straddle a hiatal hernia and may be associated with other findings of reflux esophagitis. When the characteristic features of these lesions are present on barium studies, endoscopic confirmation is unnecessary. Occasionally, however, the polyps may have a more irregular, nodular, or lobulated appearance, so a malignant lesion cannot be excluded

(Fig. 22-5B).²³ In such cases, endoscopy and biopsy are required for a definitive diagnosis.

GLYCOGENIC ACANTHOSIS

Since its original description in 1970,²⁵ glycogenic acanthosis has been recognized as a benign, non-neoplastic condition of unknown cause. Nevertheless, it is included in this chapter because it is manifested by mucosal nodules or plaques. Glycogenic acanthosis is characterized histologically by hyperplasia of squamous epithelial cells secondary to increased cytoplasmic glycogen.^{25,26} It is a common condition, with a prevalence of 3% to 15% at endoscopy.^{27–29} The lesions appear endoscopically as white mucosal plaques or nodules, ranging from 2 to 15 mm in size.^{27,28} A definitive diagnosis is made by demonstrating the characteristic glycogen-rich epithelial cells on biopsy specimens stained with periodic acid–Schiff stain.²⁵

Glycogenic acanthosis is a degenerative condition; the lesions first appear when patients are in their 40s and 50s and become larger and more numerous in patients over 60 years of age.³⁰ Glycogenic acanthosis rarely causes esophageal symptoms, and it is not associated with any known risk of malignant degeneration.³¹ This condition is therefore almost always discovered as an incidental finding on radiologic or endoscopic examination.

Radiographic Findings

Although the appearance of glycogenic acanthosis was not described on barium studies until 1981,³² it has since

Figure 22-3 Esophageal papillomatosis. There are innumerable wartlike excrescences on the esophageal mucosa. Despite the dramatic radiographic appearance, this patient had no esophageal symptoms. (Courtesy Harvey M. Goldstein, MD, San Antonio, TX.)

Figure 22-4 Adenomatous polyp in Barrett's esophagus. The polyp (arrows) originates at the gastroesophageal junction and extends into the distal esophagus above a hiatal hernia. Although this lesion could be mistaken for an inflammatory esophagogastric polyp, it is larger and more lobulated than most inflammatory polyps. The resected specimen contained a solitary focus of adenocarcinoma. (From Levine MS, Caroline D, Thompson JJ, et al: Adenocarcinoma of the esophagus: relationship to Barrett mucosa. *Radiology* 150:305–309, 1984.)

Figure 22-5 Inflammatory esophagogastric polyps. **A.** An inflammatory polyp is seen en face as a prominent fold (straight arrows) arising at the cardia and extending into the distal esophagus as a smooth, club-shaped mass (curved arrow). The radiographic findings are so characteristic that endoscopy is unwarranted. **B.** This inflammatory polyp has a more lobulated appearance (arrows), so it cannot be differentiated from an adenomatous polyp or even an adenocarcinoma (see Fig. 22-4). (B from Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

been recognized as a frequent finding on double-contrast esophagography, occurring in up to 30% of patients.^{30,31} Glycogenic acanthosis is usually manifested on double-contrast radiographs by discrete, small, rounded nodules or plaques in the mid or distal esophagus (Fig. 22-6).³¹ The lesions tend to be more obvious in the midesophagus because the distal esophagus is often obscured by pooling of barium in this region. The nodules usually range from 2 to 3 mm in size, but occasional plaques may be 1 cm or larger.^{31,32}

Differential Diagnosis

Although glycogenic acanthosis has little clinical significance, it should be distinguished from other causes of mucosal nodularity, such as superficial spreading carcinoma and reflux or *Candida* esophagitis. However, superficial spreading carcinoma is characterized by poorly defined, confluent nodules and plaques (see Chapter 23), and reflux esophagitis is characterized by innumerable tiny nodules in the distal esophagus, producing a granular appearance (see Chapter 19). In contrast, the nodules of glycogenic acanthosis are more prominent in the midesophagus and have more discrete margins with normal intervening mucosa. Although the plaques of *Candida* esophagitis may be indistinguishable on double-contrast studies from those in glycogenic acanthosis (see Chapter 20), *Candida* esophagitis occurs in immunocompromised patients with

odynophagia or dysphagia, whereas glycogenic acanthosis occurs in older individuals who are not immunocompromised and have no esophageal symptoms. Thus, the clinical history and presentation are extremely helpful for differentiating these conditions.

LEUKOPLAKIA

Oral leukoplakia is a common condition characterized by white mucosal plaques that exhibit various combinations of hyperkeratosis, epithelial dysplasia, and frank carcinoma on histologic examination. In contrast, leukoplakia rarely involves the esophagus,³³⁻³⁵ and its malignant potential in this location is unknown. Endoscopy may reveal white mucosal plaques smaller than 1 cm.³³ Rarely, the lesions may be recognized on double-contrast esophagograms as tiny nodules or plaques.^{34,35} However, most asymptomatic patients with a nodular mucosa probably have glycogenic acanthosis.³¹ Esophageal leukoplakia should therefore be considered a histologic rather than a radiologic diagnosis.

ACANTHOSIS NIGRICANS

Acanthosis nigricans is a dermatologic disorder characterized by the triad of papillomatosis, pigmentation, and hyperkeratosis. Some patients have a malignant type of acanthosis nigricans associated with adenocarcinomas of the gastrointestinal tract, ovary, lung, or breast. Esophageal involvement has occasionally been reported in patients with the malignant form of the disease.^{35,36} The esophageal lesions appear on barium studies as numerous tiny nodules.^{35,36} Because this condition rarely involves the esophagus, the diagnosis should be suggested only in patients with known acanthosis nigricans involving the skin.

Submucosal Lesions

By definition, all submucosal lesions arising in the wall of the gastrointestinal tract are intramural. Not all intramural lesions are submucosal, however, because they can also arise from the muscularis propria or even the subserosa. Despite this distinction, the terms *submucosal* and *intramural* are used interchangeably in this text based on long-standing convention.

LEIOMYOMA

Leiomyomas are the most common mesenchymal tumors of the esophagus, accounting for more than 50% of all benign esophageal neoplasms.^{2,37-39} These lesions are composed of intersecting bands of smooth muscle and fibrous tissue in a well-defined capsule and consist histologically of an interlacing or palisading pattern of spindle cells with eosinophilic cytoplasm.³⁹ Leiomyomas are usually smaller than 3 cm,³⁸ but giant lesions as large as 20 cm have been reported.^{40,41} These tumors are predominantly located in the middle and lower thirds of the thoracic esophagus, because this is the portion of the esophagus lined by smooth muscle.³⁹ Leiomyomas usually appear grossly as discrete submucosal masses, but some lesions have an exophytic, intraluminal, or even circumferential pattern of growth.

Most leiomyomas in the esophagus occur as solitary lesions, but multiple leiomyomas are present in 3% to 4% of patients.^{42,43}

Figure 22-6 Glycogenic acanthosis. A, B. In both cases, this condition is manifested by multiple small plaques and nodules in the midesophagus. The lesions tend to have a rounded appearance. *Candida* esophagitis could produce similar findings, but patients with glycogenic acanthosis are almost always asymptomatic. (A from Levine MS, Macones AJ, Laufer I: *Candida* esophagitis: Accuracy of radiographic diagnosis. *Radiology* 154:581-587, 1985; B from Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Rarely, these tumors may be associated with uterine or vulvar leiomyomas, apparently on a familial basis.^{44,45} Esophageal leiomyomas have also been documented in patients with hypertrophic osteoarthropathy, a condition characterized by clubbed fingers and toes, swollen joints, and subperiosteal new bone formation in the extremities.⁴⁶

Clinical Findings

Most patients with esophageal leiomyomas are asymptomatic, but lesions that encroach on the lumen may cause slowly worsening dysphagia or other symptoms such as substernal discomfort, vomiting, and weight loss.^{39,47} Unlike gastrointestinal stromal tumors (GISTs) in the stomach, esophageal leiomyomas rarely ulcerate, so upper gastrointestinal bleeding is extremely uncommon.⁴⁷ Because of the slowly progressive nature of the lesions, symptoms may be present for several years before these patients seek medical attention. Rarely, affected individuals may present with signs and symptoms of acute esophageal obstruction.⁴⁸ The treatment of choice for symptomatic patients is surgical enucleation of the tumor, but larger lesions may necessitate a more extensive esophageal resection. Leiomyomas typically do not recur after surgery.³⁹

Although leiomyomas are relatively common lesions in the esophagus, their malignant counterparts, leiomyosarcomas, are rare (see Chapter 24). To date, sarcomatous degeneration of an esophageal leiomyoma has not been reported. In one series, esophageal leiomyomas were followed for as long as 15 years without evidence of malignant transformation.⁴⁹ Thus, surgical removal of small leiomyomas in asymptomatic patients is probably not warranted.

Radiographic Findings

Leiomyomas that grow exophytically into the mediastinum may be recognized on chest radiographs by the presence of a mediastinal mass.⁵⁰ Rarely, these tumors may contain amorphous or punctate calcification.^{51,52} Because calcification almost never occurs in other benign or malignant tumors of the esophagus, the presence of a calcified esophageal mass should suggest a leiomyoma, although one case of a densely calcified esophageal leiomyosarcoma has been reported.⁵³

On barium esophagography, leiomyomas usually appear in profile as smooth-surfaced submucosal masses (etched in white on double-contrast radiographs) that form right angles or slightly obtuse angles with the adjacent esophageal wall (Figs. 22-7 and 22-8A) and en face as round or ovoid filling defects with splitting of the barium column around the lesion and apparent widening of the lumen (Fig. 22-8B).³⁸ These tumors may gradually enlarge over time, but ulceration is rare. Leiomyomas typically appear on computed tomography (CT) scans as homogeneous soft tissue masses,⁵⁴ but differentiation from other esophageal tumors is difficult.

Although the vast majority of leiomyomas in the esophagus occur as solitary submucosal masses, esophagography may occasionally reveal multiple lesions^{42,43} or even annular lesions with varying degrees of obstruction.³⁹ Rarely, leiomyomas may be giant intraluminal masses that are attached to the upper thoracic or cervical esophagus by a long pedicle.⁵⁵ However, most pedunculated intraluminal tumors in the esophagus contain a variety of other mesenchymal elements; these tumors have therefore been classified together as fibrovascular polyps (see later, “Fibrovascular Polyp”). Rarely, distal esophageal

Figure 22-7 Esophageal leiomyomas. A, B. The lesions (arrows) have a smooth surface (etched in white) and slightly obtuse borders characteristic of submucosal masses.

leiomyomas may directly involve the gastric cardia and fundus.⁵⁶

Differential Diagnosis

Most submucosal masses in the esophagus are leiomyomas. However, other unusual intramural tumors such as granular cell tumors, lipomas, hemangiomas, and neurofibromas may produce identical radiographic findings (see later). Cystic lesions such as congenital duplication cysts and acquired retention cysts may also appear as submucosal masses on barium studies (see later, “Cysts”). Even an isolated esophageal varix may resemble a submucosal tumor, but effacement or obliteration of the lesion by esophageal distention should suggest its vascular origin (see Chapter 25). Because leiomyomas usually occur as solitary lesions in the esophagus, the presence of multiple submucosal masses should raise the possibility of multiple granular cell tumors or hemangiomas or malignant conditions such as lymphoma, leukemia, or Kaposi’s sarcoma involving the esophagus (see Chapter 24). In contrast, hematogenous metastases almost never involve the esophagus.

Leiomyomas should be distinguished from extramural lesions that are extrinsically compressing or indenting the esophagus. When viewed in profile, extrinsic lesions tend to have more obtuse, gently sloping borders than intramural lesions. Another useful criterion for differentiating these lesions is the spheroid sign, which is based on the principle that the estimated center of the mass should lie outside the projected contour of the esophagus for extramural lesions but inside the projected contour for intramural lesions.⁵⁷ When the radiographic findings are equivocal, CT may be helpful for differentiating a submucosal tumor from a mediastinal mass compressing the esophagus.⁵⁵

Figure 22-8 Esophageal leiomyoma. **A.** Tangential view reveals the characteristic features of a submucosal lesion. The outer margin of the leiomyoma is seen as a soft tissue shadow (arrows) abutting the lung. **B.** En face view shows a smooth, rounded filling defect in the esophagus, with splitting of barium around the lesion. The esophagus appears widened at this level. (Courtesy Marc P. Banner, MD, Philadelphia.)

GASTROINTESTINAL STROMAL TUMOR

In the past, almost all mesenchymal neoplasms in the esophagus were thought to be benign leiomyomas, but recent studies have shown that GISTs are more common in the esophagus than previously recognized.⁵⁸⁻⁶¹ Like leiomyomas, these tumors consist histologically of multiple spindle cells, but GISTs are characterized by their unique immunohistochemical expression of CD117, also known as C-KIT.⁶² Immunohistochemical testing is therefore extremely helpful for differentiating GISTs from leiomyomas because only GISTs are positive for CD117 and CD34.³⁹ Patients with esophageal GISTs may be asymptomatic, or they may present with dysphagia, depending on the size of the lesion and how much it encroaches on the lumen. Unlike leiomyomas, which are always benign, however, esophageal GISTs appear to have a malignant potential similar to that of GISTs elsewhere in the gastrointestinal tract (with the development of recurrent tumor after surgical resection), so more aggressive management of these tumors may be warranted.⁶¹ Patients with esophageal GISTs could also benefit from adjuvant treatment with imatinib (Gleevec), a tyrosine kinase inhibitor.⁶¹ Thus, differentiation of leiomyomas from GISTs in the esophagus has important ramifications for patient management.

Radiographic Findings

Esophageal GISTs typically appear on barium studies as discrete submucosal masses that are indistinguishable from leiomyomas or other mesenchymal tumors in the esophagus (Fig. 22-9).⁶¹ Like GISTs elsewhere in the gastrointestinal tract, however, esophageal GISTs tend to be larger, more heterogeneous (secondary to cystic changes and necrosis), and more enhancing lesions than esophageal leiomyomas on contrast-enhanced CT (Fig. 22-10A).⁶¹ Esophageal GISTs also have uniform and marked fluorine-18-deoxyglucose (FDG) avidity on positron emission tomography (PET)/CT scans (Fig. 22-10B), another

Figure 22-9 Esophageal GIST. The lesion appears as a discrete submucosal mass (arrow) that is indistinguishable from an esophageal leiomyoma on barium esophagography. (From Winant A, Gollub MJ, Shia J, et al: Imaging and clinicopathologic features of esophageal gastrointestinal stromal tumors. *AJR* 203:306-314, 2014.)

Figure 22-10 Esophageal GIST. **A.** Contrast-enhanced axial CT scan shows a large, heterogeneous, well-circumscribed mass that is inseparable from the left lateral wall of the distal esophagus. Note peripheral enhancing solid components (short arrows) and large internal cystic areas (long arrows). **B.** Coronal PET/CT scan (maximum intensity projection) shows uniform and marked FDG avidity of large left paraesophageal mass (arrows). The findings on CT and PET enable differentiation of GISTs from leiomyomas. (From Winant A, Gollub MJ, Shia J, et al: *Imaging and clinicopathologic features of esophageal gastrointestinal stromal tumors*. *AJR* 203:306–314, 2014.)

useful imaging feature for differentiating these tumors from leiomyomas.⁶¹ Radiologists should be familiar with the imaging and clinicopathologic features of esophageal GISTs and of the importance of differentiating these lesions from leiomyomas because of their apparent malignant potential.

LEIOMYOMATOSIS AND IDIOPATHIC MUSCULAR HYPERTROPHY

Esophageal leiomyomatosis is a rare benign condition in which neoplastic proliferation of smooth muscle causes marked circumferential thickening of the esophageal wall, usually in the distal esophagus.^{63–65} This condition is found predominantly in children and young adults who present with long-standing dysphagia.⁶⁵ Esophageal leiomyomatosis can occur sporadically or on a familial basis with autosomal dominant inheritance.^{66,67} In some cases, this condition is associated with widespread visceral leiomyomatosis^{68–70} or hereditary nephritis (Alport's syndrome).^{66,67,69,71} Depending on the extent of the lesion, an esophagectomy or esophagogastrectomy is almost always curative.^{63,67}

Idiopathic muscular hypertrophy of the esophagus is closely related to esophageal leiomyomatosis.^{72–75} This condition is characterized by non-neoplastic thickening of smooth muscle in the esophageal wall, possibly as a response to severe esophageal spasm. In contrast to patients with leiomyomatosis, these individuals usually remain asymptomatic or present with dysphagia during late adulthood.^{73,75} Occasionally, however, patients with idiopathic muscular hypertrophy of the esophagus may have such severe dysphagia that an esophagectomy is required.

Radiographic Findings

Esophageal leiomyomatosis may be manifested on barium studies by smooth, tapered narrowing of the distal esophagus with decreased or absent esophageal peristalsis, mimicking the appearance of primary achalasia (Fig. 22-11A).^{63,65,71} However, the narrowed segment tends to be longer than that in achalasia, and leiomyomatosis is sometimes associated with relatively symmetric paracardiac defects in the gastric fundus because of bulging of this thickened mass of muscle into the proximal stomach (see Fig. 22-11A).⁶⁵ CT may reveal marked circumferential thickening of the distal esophageal wall, resembling the findings of secondary achalasia caused by metastatic tumor at the gastroesophageal junction (Figs. 22-11B and C).⁶⁵ However, leiomyomatosis usually occurs in children or adolescents with long-standing dysphagia, whereas secondary achalasia occurs in older adults with recent onset of dysphagia and weight loss.⁷⁶ Thus, despite its rarity, the diagnosis of esophageal leiomyomatosis can usually be suggested on the basis of the clinical and radiographic findings.

Idiopathic muscular hypertrophy of the esophagus may be manifested on esophagography by a corkscrew appearance with multiple lumen-obliterating, nonperistaltic contractions.^{72–74} In other cases, this condition may produce an achalasia-like appearance, with tapered narrowing of the distal esophagus and proximal dilation on barium studies (Fig. 22-12A)^{73,75} and marked circumferential thickening of the distal esophageal wall on CT (Fig. 22-12B).^{73,75} The radiographic findings may therefore be indistinguishable from those of esophageal leiomyomatosis. However, patients with idiopathic muscular hypertrophy of the esophagus usually present later in life than those with

Figure 22-11 Esophageal leiomyomatosis. **A.** Barium study shows smooth, tapered narrowing of the distal esophagus (black arrows), resembling achalasia. However, the narrowed segment is longer than that typically seen in achalasia. Also, the thickened muscle is seen bulging into the gastric fundus as a soft tissue mass (white arrow). **B.** Axial CT scan shows a mass of relatively low soft tissue attenuation (large arrows) surrounding the distal esophagus with a slitlike collection of contrast material (small arrow) in the compressed esophageal lumen. **C.** More caudad axial CT scan shows this thickened mass of muscle bulging into the gastric fundus (arrows) on both sides of the cardia. (From Levine MS, Buck JL, Pantongrag-Brown L, et al: *Esophageal leiomyomatosis*. *Radiology* 199:533–536, 1996.)

Figure 22-12 Idiopathic muscular hypertrophy of the esophagus. **A.** Barium study reveals a markedly dilated esophagus with relatively abrupt narrowing (arrow) near the gastroesophageal junction. **B.** Axial CT scan near the level of the gastroesophageal junction shows massive thickening of the distal esophageal wall and narrowing of the lumen (closed arrows). An air-contrast level (open arrow) is present in the dilated esophagus to the right. At surgery, there was a markedly thickened esophageal wall because of localized muscular hypertrophy without evidence of tumor. The radiographic findings in this case resemble those of esophageal leiomyomatosis shown in Figure 22-11. (Courtesy Richard L. Baron, MD, Pittsburgh, PA.)

leiomyomatosis, so the clinical history is helpful for differentiating these conditions.

FIBROVASCULAR POLYP

Fibrovascular polyps are rare, benign, tumor-like lesions characterized by the development of pedunculated intraluminal masses that can grow to gigantic sizes in the esophagus. The lesions consist histologically of varying amounts of fibrovascular and adipose tissue covered by normal squamous epithelium.⁷⁷⁻⁷⁹ Depending on the predominant mesenchymal components, these lesions have variously been called hamartomas, fibromas, lipomas, fibrolipomas, fibromyxomas, and fibroepithelial polyps.⁸⁰ However, they have all now been classified together as *fibrovascular polyps*,^{79,80} a term recommended by the World Health Organization in its histologic classification of tumors.⁸¹

Fibrovascular polyps almost always arise in the cervical esophagus near the level of the cricopharynx.⁷⁸⁻⁸⁰ They probably originate from loose submucosal tissue in the cervical esophagus, gradually elongating over a period of years as they are dragged inferiorly into the middle or distal third of the esophagus by esophageal peristalsis until the intraluminal portion of the mass has attained gigantic proportions.⁷⁶ Occasionally, fibrovascular polyps can even prolapse through the cardia into the gastric fundus.⁷⁷ Regardless of the size of the polyp, its proximal end is almost always attached to the cervical esophagus by a discrete pedicle.⁸²

Clinical Findings

Fibrovascular polyps usually occur in older men who present with long-standing dysphagia that slowly progresses over a

period of years as the intraluminal portion of the polyp gradually enlarges.⁸³ Other patients may develop wheezing or inspiratory stridor because of compression of the adjacent trachea by the distended esophagus.^{77,78,83} Occasionally, these individuals may have a spectacular clinical presentation with regurgitation of a fleshy mass into the pharynx or mouth.^{77,79,80,82} Some distraught patients have even tried to bite off the lesion with their teeth or remove it manually with their fingers. Apart from the bizarre clinical features of this entity, regurgitated fibrovascular polyps in the pharynx are potentially life-threatening because they have rarely been known to occlude the larynx, causing asphyxia and sudden death.⁸⁴

Malignant degeneration of fibrovascular polyps is thought to be extremely rare. Nevertheless, removal of these lesions is recommended because of the progressive and eventually debilitating nature of the symptoms and the theoretical risk of asphyxia and sudden death. Small fibrovascular polyps may be resected endoscopically, but large tumors should be removed surgically because significant bleeding may occur when the stalk is transected.⁸³

Radiographic Findings

Fibrovascular polyps can sometimes be recognized on chest radiographs by the presence of a right-sided superior mediastinal mass, anterior tracheal bowing, or both.⁸³ The polyps usually appear on esophagography as smooth, expansile, sausage-shaped intraluminal masses that arise in the cervical esophagus and extend into the upper or middle third of the thoracic esophagus (Fig. 22-13A).^{77,78,80,85} Occasionally, these lesions may show varying degrees of lobulation (Fig. 22-14A)⁷⁹ or may extend into the distal esophagus or even the gastric fundus.^{77,83} Although most fibrovascular polyps have a site of

Figure 22-13 Fibrovascular polyp. **A.** Barium study shows a smooth, sausage-shaped mass (arrows) expanding the lumen of the upper thoracic esophagus. This lesion has the classic appearance of a fibrovascular polyp. **B.** Axial CT scan shows an expansile mass (arrow) in the thoracic esophagus with a thin rim of contrast material surrounding the lesion, confirming its intraluminal location. The fat density of the polyp is caused by an abundance of adipose tissue in this lesion. (From Levine MS, Buck JL, Pantongrag-Brown L, et al: Fibrovascular polyps of the esophagus: Clinical, radiographic, and pathologic findings in 16 patients. *AJR* 166:781-787, 1996.)

Figure 22-14 Fibrovascular polyp. **A.** Barium study shows an expansile mass extending into the distal thoracic esophagus. In contrast to the polyp in Figure 22-13A, this lesion has a lobulated contour, so it could be mistaken for a malignant esophageal tumor. **B.** Axial CT scan also shows an expansile mass (arrows) in the esophagus with intraluminal contrast material surrounding the lesion. In this case, note the heterogeneous appearance of the polyp with areas of fat juxtaposed with areas of soft tissue density. (From Levine MS, Buck JL, Pantongrag-Brown L, et al: Fibrovascular polyps of the esophagus: Clinical, radiographic, and pathologic findings in 16 patients. *AJR* 166:781–787, 1996.)

attachment in the cervical esophagus, it is often difficult to demonstrate the proximal pedicle on barium studies.⁸³

Fibrovascular polyps containing an abundance of adipose tissue may appear on CT as fat density lesions that expand the lumen of the esophagus, with a thin rim of contrast surrounding the polyp, confirming its intraluminal location (Fig. 22-13B).^{83,86–88} Polyps containing equal amounts of adipose and fibrovascular tissue may appear as heterogeneous lesions with focal areas of fat density juxtaposed with areas of soft tissue density (Fig. 22-14B), and polyps containing an abundance of fibrovascular tissue may appear as areas of soft tissue density with a paucity of fat.⁸³ Thus, fibrovascular polyps may be manifested by a spectrum of findings on CT, depending on the amount of adipose and fibrovascular tissue in these lesions. Occasionally, a centrally located feeding artery within the polyp may show contrast enhancement on CT.⁸⁹

Fibrovascular polyps containing an abundance of adipose tissue are characterized by high signal intensity on T1-weighted magnetic resonance imaging (MRI).⁸⁷ Such polyps may be manifested on endoscopic sonography by increased echogenicity because of their high fat content.^{79,90}

Differential Diagnosis

Despite their size, fibrovascular polyps are sometimes difficult to diagnose on barium studies. These lesions can be mistaken for giant, coalescent air bubbles, extrinsic masses compressing the esophagus, or other polypoid intraluminal tumors, such as spindle cell carcinomas or primary malignant melanomas of the esophagus, particularly if the polyps are lobulated (see Chapter 24). However, these malignant tumors are often confined to the mid or distal thoracic esophagus, whereas fibrovascular polyps always extend superiorly into the cervical

esophagus. When fibrovascular polyps contain an abundance of adipose tissue, the typical findings on CT or MRI should suggest the correct diagnosis.

GRANULAR CELL TUMOR

Since its original description by Abrikossoff in 1926, granular cell myoblastoma has been recognized as a rare benign tumor that predominantly involves the skin, tongue, breast, and subcutaneous tissues.^{91,92} Abrikossoff believed that these tumors had a myogenic origin, but pathologic data suggest that they have a neural derivation, arising from Schwann cells.⁹³ The term *granular cell myoblastoma* is therefore a misnomer, and the lesions have more correctly been described as *granular cell tumors*.^{94–96} Histologically, these lesions consist of sheets of polygonal tumor cells containing an eosinophilic-staining granular cytoplasm.^{94,96} The tumors are covered by hyperplastic but otherwise normal squamous epithelium. About 7% of granular cell tumors are located in the gastrointestinal tract, and one third of these lesions are located in the esophagus.^{92,95}

Most granular cell tumors in the esophagus occur as solitary lesions, ranging from 0.5 to 2.0 cm in size.⁹⁴ Some larger lesions may cause dysphagia.^{94,96,97} The treatment of choice for symptomatic patients with granular cell tumors is local excision because these tumors almost never recur after endoscopic or surgical removal.^{92,94–97} In contrast, asymptomatic patients with granular cell tumors found by endoscopic biopsy probably do not require surgery because of the negligible risk of malignant degeneration.^{97,98} Occasionally, the findings on endoscopic biopsy specimens can be mistaken for squamous cell carcinoma as a result of pseudoepitheliomatous hyperplasia of the overlying squamous mucosa.^{94,96,98}

Radiographic Findings

Granular cell tumors usually appear on esophagography as small, round or ovoid submucosal masses in the distal or, less commonly, middle third of the esophagus (Fig. 22-15).^{94,96} Because of their typical submucosal appearance, they are most often mistaken for leiomyomas.⁹⁴ Occasionally, granular cell tumors arising at the gastric cardia may be manifested by a polypoid or submucosal mass that distorts or obliterates the normal anatomic landmarks of this region.⁹⁶ Rarely, multiple granular cell tumors may be present in the esophagus or stomach (Fig. 22-16).^{97,99}

LIPOMA

The esophagus is the least common site of involvement by lipomas in the gastrointestinal tract. These tumors may appear on barium studies as discrete submucosal masses (Fig. 22-17) or, more commonly, as pedunculated, intraluminal masses.¹⁰⁰⁻¹⁰³ Rarely, pedunculated lipomas in the upper esophagus can be regurgitated into the pharynx, causing asphyxia and sudden death.¹⁰² Lipomas in the esophagus may be diagnosed preoperatively by their characteristic fat density on CT.¹⁰⁴

Figure 22-15 Granular cell tumor. A smooth submucosal mass (arrow) is seen in the midesophagus. This lesion cannot be differentiated from leiomyomas or other submucosal lesions in the esophagus. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

HEMANGIOMA

The esophagus is the least common site of involvement by vascular tumors in the gastrointestinal tract. Rarely, multiple esophageal hemangiomas may be found in patients with Osler-Weber-Rendu disease, a hereditary disorder characterized by telangiectasias of the face, lips, and mucous membranes.¹⁰⁵ However, most vascular tumors in the esophagus are solitary cavernous hemangiomas.¹⁰⁶ These highly vascular lesions may occasionally ulcerate, causing massive hematemesis and fatal exsanguination.¹⁰⁶ Esophageal hemangiomas usually appear on barium studies as smooth or slightly lobulated submucosal masses that are indistinguishable from other, more common benign intramural tumors.¹⁰⁷ Because of the risk of significant bleeding, the treatment of choice is surgical enucleation of the lesion.^{106,107}

HAMARTOMA

Esophageal hamartomas are rare benign tumors characterized histologically by metaplastic respiratory epithelium and islets of cartilage in a fibrous stroma.^{108,109} These tumors usually appear on esophagography as pedunculated intraluminal masses that are indistinguishable from fibrovascular polyps.¹⁰⁸ Rarely, multiple esophageal hamartomas may be found in

Figure 22-16 Multiple granular cell tumors. The lesions are seen as discrete submucosal masses (arrows) in the middle and distal thirds of the esophagus. This patient had additional granular cell tumors in the stomach. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 22-17 Esophageal lipoma. This patient had a discrete submucosal mass (arrows) indistinguishable from leiomyomas or other intramural tumors. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 22-18 Cowden's disease with multiple hamartomatous polyps in the esophagus. The lesions appear as tiny nodular elevations on the mucosa. (Courtesy Stephen W. Trenkner, MD, Minneapolis.)

patients with Cowden's disease or multiple hamartoma syndrome, an autosomal dominant hereditary disorder characterized by multiple hamartomatous malformations of ectodermal, mesodermal, and endodermal layers as well as benign or malignant tumors of the skin, breast, gastrointestinal tract, and thyroid.^{110,111} Esophageal involvement may be manifested by innumerable tiny hamartomatous polyps in the esophagus, producing a diffusely nodular mucosa on double-contrast images (Fig. 22-18).^{110,111} When the esophagus is involved by this disease, widespread polyposis of the gastrointestinal tract is usually present. Cowden's disease should be distinguished from other polyposis syndromes, which almost never involve the esophagus.

OTHER MESENCHYMAL TUMORS

Other rare mesenchymal tumors in the esophagus include fibromas, neurofibromas, and myxofibromas.⁴⁷ These lesions usually appear on barium studies as discrete intramural masses that are indistinguishable from leiomyomas. When mesenchymal tumors contain a substantial amount of fibrovascular or adipose tissue, they can slowly elongate, forming pedunculated intraluminal masses. Because the latter tumors have characteristic clinical, radiographic, and pathologic findings, they have

been classified together as fibrovascular polyps (see earlier, "Fibrovascular Polyp").

CYSTS

Duplication Cyst

Esophageal duplication cysts constitute about 20% of all gastrointestinal tract duplications.¹¹² These cysts result from abnormal embryologic development in which nests of cells are sequestered from the primitive foregut.¹¹³ The lesions may be classified as cystic duplications or, less commonly, as tubular duplications. About 60% are located in the lower half of the posterior mediastinum, often projecting to the right of the distal esophagus.¹¹² Although most duplication cysts are noncommunicating, tubular duplications occasionally may communicate directly with the esophageal lumen. Histologically, duplication cysts contain a mucosa, submucosa, and muscularis propria and are lined by ciliated columnar or cuboidal epithelium.¹¹³ In about 40% of cases, ectopic gastric mucosa is found in the lining of the cyst wall.¹¹²

Esophageal duplication cysts may be detected as an isolated finding, but some lesions are associated with vertebral anomalies, esophageal atresia, or other congenital anomalies.¹¹²

Most adults with esophageal duplication cysts are asymptomatic, but symptoms may occasionally be caused by obstruction, bleeding, or infection of the cyst.^{114,115} Bleeding or perforation is more likely to occur when ectopic gastric mucosa is present in the cyst wall.¹⁰⁸

Radiographic Findings. Esophageal duplication cysts can sometimes be recognized on chest radiographs by the presence of a right lower mediastinal mass. Chest radiographs may occasionally reveal associated vertebral anomalies.¹¹² The cysts usually appear on esophagography as discrete submucosal masses that are indistinguishable from solid intramural tumors (Fig. 22-19). Rarely, communicating duplications may be manifested by tubular, branching outpouchings from the esophagus as a result of filling of these structures with barium (Fig. 22-20).¹¹⁶

Cross-sectional imaging studies can sometimes aid in the diagnosis of esophageal duplication cysts. Because these cysts are fluid-filled structures, they typically have homogeneous low attenuation on CT scans and high-signal intensity on T2-weighted MR images (Fig. 22-21).^{117,118} Endoscopic ultrasound may reveal a smooth, spherical or, less commonly, tubular

Figure 22-19 Duplication cyst. There is a large submucosal mass in the distal esophagus. The lateral border of the cyst (arrows) is readily visible where it abuts the right lung. Duplication cysts typically occur in this location. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 22-20 Duplication cyst. Barium study shows the rare communicating form of duplication cyst as a tubular, branching outpouching (arrows) from the midesophagus. (Courtesy Marie Latour, MD, Philadelphia.)

Figure 22-21 Duplication cyst. Axial T2-weighted MR image shows a fluid-filled, cystic mass (arrow) with high signal intensity in the right side of the mediastinum. (From Rafal RB, Markisz JA: *Magnetic resonance imaging of an esophageal duplication cyst*. *Am J Gastroenterol* 86:1809–1811, 1991.)

structure with a hyperechoic inner mucosa layer and a hypoechoic outer muscular layer.¹¹⁹ Technetium Tc 99m pertechnetate scintigraphy may help confirm the diagnosis of an esophageal duplication cyst containing ectopic gastric mucosa.¹¹²

Retention Cyst

Acquired esophageal cysts are much less common than congenital duplication cysts. They probably result from abnormal dilatation of columnar epithelial-lined mucous glands in the submucosa and are therefore called *esophageal retention cysts* or *mucocoeles*.¹²⁰⁻¹²³ Histologically, these cysts are lined by non-ciliated columnar or cuboidal epithelium.¹¹⁸ The pathogenesis of these lesions is uncertain, but it has been postulated that submucosal glands in the esophagus may become cystically dilated because of mechanical obstruction of the excretory ducts by mucus plugs or abnormally viscous mucus.^{120,121} This entity has sometimes been described as *esophagitis cystica*, but a more appropriate descriptive term is *esophageal retention cyst* because only minimal inflammatory change may be present in these lesions.^{120,121}

Esophageal retention cysts may appear on barium studies as solitary or, more commonly, multiple submucosal masses in the distal esophagus (Fig. 22-22).^{120,121,123} As a result, the lesions cannot be distinguished radiographically from other submucosal tumors. These patients are usually asymptomatic, however, so most esophageal retention cysts are discovered as incidental findings at autopsy.¹²⁰

Figure 22-22 Esophageal retention cyst. The lesion is seen as a discrete submucosal mass (arrows) indistinguishable from leiomyomas or other intramural lesions. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Treatment

Surgery
Radiation Therapy
Chemoradiation Therapy

Esophageal carcinoma constitutes only about 1% of all cancers and 7% of cancers in the gastrointestinal (GI) tract.¹ Nevertheless, it is a deadly disease, with an overall 5-year survival rate of only about 15%.² At one time, most malignant tumors of the esophagus were thought to be squamous cell carcinomas, but adenocarcinomas arising in Barrett's esophagus have increased dramatically in incidence since the 1970s. Because of important differences between these tumors, the chapter is divided into separate sections on squamous cell carcinoma and adenocarcinoma of the esophagus.

Squamous Cell Carcinoma

EPIDEMIOLOGY

Esophageal carcinoma is predominantly a disease of older men, with a male-to-female ratio of almost 4:1 and a peak incidence between 65 and 74 years of age.² The development of squamous cell carcinoma of the esophagus is a multifactorial

process associated with a variety of risk factors, including tobacco and alcohol consumption, obesity, nutritional deficiencies, exposure to various environmental carcinogens, and geographic location.

Two of the major risk factors for the development of esophageal cancer in the United States are tobacco and alcohol consumption.^{3,4} Tobacco and alcohol appear to have a synergistic effect, so people who smoke and drink have even higher rates of esophageal cancer.⁵ Although tobacco smoke is known to contain a variety of carcinogens, the development of esophageal carcinoma in alcoholics may be related to other factors such as poor health and nutritional deficiencies. Obesity also has been recognized as an important risk factor for the development of esophageal cancer.^{4,6}

Squamous cell carcinoma of the esophagus has striking geographic variations, with the highest incidences reported in an Asian esophageal cancer belt stretching from eastern Turkey and northern Iran to India and northern China.⁷ A high incidence has also been reported in South Africa and France. These regional variations in the frequency of esophageal cancer have been attributed primarily to environmental rather than hereditary factors. Dietary habits in particular have been implicated because people living in areas with a high incidence of esophageal cancer often have diets high in starch and low in fresh fruits and vegetables.⁷ Other environmental factors may also have a role in cancer pathogenesis. For example, nitrosamines and other nitroso compounds are potent carcinogens that occur in high concentrations in the food and water supply of parts of northern China.⁸ Epidemiologic studies in China and South Africa have shown that these areas also have unusually low levels of molybdenum in the soil.^{9,10} Because molybdenum is required for the metabolism of nitrite to ammonia, low levels of molybdenum in the soil could lead to the accumulation of nitrites and potentially carcinogenic nitrosamines in plants consumed by humans. The high prevalence of esophageal cancer in parts of Saudi Arabia has been attributed to contamination of drinking water by impurities such as petroleum oils.¹¹ Other substances such as tannin, betel leaves, and asbestos fibers have also been implicated in the development of esophageal cancer.¹²⁻¹⁴

Attention has also been focused on the potential role of human papillomavirus (HPV) in the pathogenesis of esophageal cancer, particularly in high-risk areas such as China and South Africa. In studies from China, HPV has been isolated by *in situ* hybridization techniques in 25% to 50% of esophageal cancer specimens.^{15,16} These data suggest that HPV may be an important contributing factor in the development of esophageal cancer.

PREDISPOSING CONDITIONS

Conditions that are thought to predispose patients to the development of squamous cell carcinoma of the esophagus include

achalasia, lye strictures, head and neck tumors, celiac disease, Plummer-Vinson syndrome, radiation, and tylosis. Because of the increased risk of developing esophageal cancer, periodic surveillance has often been advocated for patients with these conditions.

Achalasia

Achalasia is thought to be a premalignant condition associated with an increased risk of developing esophageal carcinoma. In various studies, the prevalence of esophageal cancer in patients with long-standing achalasia has ranged from 2% to 8%.¹⁷⁻¹⁹ Malignant degeneration presumably occurs as a result of chronic stasis esophagitis caused by retained food and debris in a dilated, obstructed esophagus.¹⁷⁻²⁰ Most patients have had achalasia for at least 20 years before the development of cancer.^{17,19,20} Unfortunately, a neoplastic lesion growing inside a massively dilated esophagus may not cause symptoms until it is an advanced, unresectable tumor.^{19,21} As a result, some authors believe that patients with long-standing achalasia should undergo annual surveillance with barium studies or endoscopy to detect developing cancers at the earliest possible stage.^{17,20,21} However, one study failed to show an increased cancer risk in these patients,²² so not all investigators accept the need for surveillance.

Lye Strictures

Patients with chronic lye strictures have an increased risk of developing esophageal carcinoma. In various studies, the prevalence of cancer has ranged from 2% to 16%.^{23,24} Although the pathogenesis is uncertain, it has been postulated that chronic inflammation and scarring from caustic esophagitis predispose these patients to the development of esophageal carcinoma. The average latent period between the ingestion of lye and development of cancer is 40 to 45 years.^{25,26} These patients usually seek medical attention for recurrent or suddenly worsening dysphagia many years after lye ingestion. Carcinomas arising in lye strictures have a better prognosis than most esophageal cancers, with 5-year survival rates of 8% to 33%.²⁵ This more favorable prognosis may be related to the presence of dense scar tissue surrounding the tumor, which prevents early invasion of adjacent mediastinal structures.^{25,26} Some investigators advocate periodic surveillance of patients with long-standing lye strictures, but these individuals are often in a socioeconomic group least likely to be compliant with surveillance programs.

Head and Neck Tumors

Patients with primary squamous cell carcinomas of the oral cavity, pharynx, and larynx have a substantially increased risk of developing separate primary esophageal carcinomas. In various studies, 2% to 8% of patients with head and neck tumors who underwent endoscopic surveillance were found to have synchronous esophageal cancers.²⁷⁻²⁹ This association has been attributed to common predisposing factors, primarily smoking and drinking because exposure to tobacco and alcohol considerably increases the risk of squamous cell carcinoma in both areas.³⁰ Radiologic or endoscopic evaluation of the esophagus has therefore been advocated in the initial work-up of all patients with head and neck tumors. Many of these synchronous esophageal cancers are small, asymptomatic lesions, so screening tests may detect such tumors at an early stage, when they are potentially curable.²⁹ Discovery of an advanced

lesion in the esophagus is also important because radical head and neck surgery may no longer be appropriate in these patients. The risk of developing subsequent metachronous esophageal carcinomas is also considerably increased in patients with head and neck tumors. Some form of ongoing surveillance is therefore required to detect metachronous esophageal lesions.

Celiac Disease

Celiac disease (nontropical sprue) is thought to be associated with an increased risk of developing esophageal carcinoma.^{31,32} The pathogenesis of cancer is uncertain, but it has been postulated that carcinogens are absorbed through an atrophic jejunal mucosa in patients with advanced celiac disease.³² Most patients have long-standing disease; malabsorption is present for an average of 35 years before the development of cancer.³¹ Some investigators therefore advocate radiologic or endoscopic surveillance of the esophagus in these patients.

Plummer-Vinson Syndrome

Plummer-Vinson, or Paterson-Kelly, syndrome is characterized by iron deficiency anemia, glossitis, postcricoid webs, and dysphagia.³³ This syndrome has been described primarily in women of Scandinavian origin. The prevalence of hypopharyngeal or esophageal carcinoma in Plummer-Vinson syndrome has ranged from 4% to 16%.^{33,34} Almost all such cancers are associated with postcricoid webs.³³ Radiologic or endoscopic examinations are therefore required to differentiate webs from superimposed hypopharyngeal or esophageal carcinomas in these patients.

Radiation

Esophageal cancer is a rare complication of chronic radiation injury to the esophagus. Most cases have occurred in the cervical or upper thoracic esophagus after radiation doses of 20 to 50 Gy to the mediastinum or neck.^{35,36} In one study, women who received radiation therapy for carcinoma of the breast were found to have an increased risk of esophageal carcinoma.³⁷ In general, however, the average latent period between radiation therapy and the development of cancer is about 30 years.³⁶ It is therefore difficult to prove that these lesions are not coincidental cancers arising in a previously irradiated area.

Tylosis

Tylosis (Howel-Evans syndrome) is an extremely rare, hereditary, autosomal dominant disorder characterized by hyperkeratosis of the palms and soles, with thickening and fissuring of the skin. This disorder is associated with an extraordinarily high risk of developing esophageal cancer.³⁸⁻⁴⁰ In one study, 95% of patients with tylosis had esophageal cancer by 65 years of age.³⁹ Most of these patients are found to have advanced, unresectable tumors at the time of clinical presentation. However, asymptomatic individuals with tylosis may have hyperkeratotic esophageal plaques containing foci of dysplasia, intramucosal carcinoma, or invasive carcinoma.⁴⁰ Thus, periodic surveillance of asymptomatic family members has been advocated to detect premalignant lesions before the development of overt carcinoma. Because of the high likelihood of developing esophageal cancer, a prophylactic esophagectomy is sometimes justified for these patients.

PATHOLOGY

Gross Features

Squamous cell carcinomas of the esophagus may appear grossly as infiltrating, polypoid, ulcerative, or superficial spreading lesions. Infiltrating lesions, the most common type, cause irregular narrowing and constriction of the lumen. Polypoid lesions are lobulated or fungating masses that protrude into the lumen. Primary ulcerative lesions are relatively flat masses in which the bulk of the tumor is necrotic and ulcerated. Less frequently, superficial spreading lesions may extend longitudinally in the wall, without invading beyond the mucosa or submucosa. Patients with superficial spreading carcinomas tend to have a better prognosis than those with more invasive forms of esophageal cancer.

Histologic Features

About 50% of esophageal cancers are squamous cell carcinomas, and the remaining 50% are adenocarcinomas arising in Barrett's mucosa.⁴¹ Other less common malignant tumors of the esophagus are discussed in Chapter 24.

At the time of clinical presentation, most squamous cell carcinomas of the esophagus are advanced lesions that have already invaded regional lymph nodes or other local or distant structures. As a result, affected individuals have a dismal prognosis, with overall 5-year survival rates of only about 15%.² In contrast, early esophageal cancers are relatively curable lesions, with 5-year survival rates of more than 90%.^{42,43} According to the Japanese Society for Esophageal Diseases, early esophageal cancer is defined histologically as cancer limited to the mucosa or submucosa without lymph node involvement.⁴⁴ Many of these cases have been reported in the Chinese literature as a result of mass screening of the adult population because of the high incidence of esophageal cancer in that country.^{8,45}

Considerable confusion exists in the literature regarding the terminology for "early" cancer. The terms *early esophageal cancer*, *superficial esophageal cancer*, and *small esophageal cancer* have been used interchangeably to describe malignant esophageal tumors diagnosed at an early stage. However, these lesions should not be considered synonymous because they have different histopathologic features that alter the prognosis of this disease. According to the Japanese Society for Esophageal Diseases, superficial esophageal cancer is confined to the mucosa or submucosa but, unlike patients with early esophageal cancer, patients with superficial cancers may have lymph node metastases.⁴⁴ *Small esophageal cancer* is another term used to describe tumors smaller than 3.5 cm, regardless of the depth of invasion or the presence or absence of lymph node metastases.^{46,47} Previous studies have shown that the 5-year survival for esophageal cancer decreases markedly when regional lymph nodes are involved by tumor.^{48,49} Thus, some superficial or small esophageal cancers may be early lesions histologically, whereas others may have already invaded regional lymph nodes, with a prognosis comparable to that of advanced esophageal cancer.^{47,49}

Distribution

Squamous cell carcinomas of the esophagus tend to be located in the upper, middle or, less commonly, distal third of the esophagus.^{48,50} Unlike adenocarcinomas arising in Barrett's mucosa, squamous cell carcinomas of the distal esophagus

almost never invade the stomach, and there is usually a discrete segment of normal esophagus between the tumor and gastric cardia.

ROUTES OF SPREAD

Esophageal carcinoma may invade local, regional, or distant structures by various pathways, including direct extension, lymphatic spread, and hematogenous metastases.

Direct Extension

Because the esophagus lacks a serosa and is attached to neighboring structures by only a loose adventitia, there is no anatomic barrier to prevent rapid spread of tumor into the adjacent mediastinum. As a result, esophageal cancer has a marked tendency to invade contiguous structures in the neck or chest, such as the thyroid, larynx, trachea, bronchi (usually the left main bronchus), aorta, thoracic duct, lung, pericardium, and diaphragm.^{48,50} The tracheobronchial tree is a particularly common site of involvement; tracheoesophageal or esophagobronchial fistulas develop in 5% to 10% of all patients with esophageal cancer.^{51,52} Rarely, aortoesophageal fistulas or even esophagopericardial fistulas may occur as a terminal complication of esophageal cancer caused by aortic or pericardial invasion by tumor.^{53,54}

Lymphatic Spread

Lymphatic metastases are found in up to 75% of patients with esophageal cancer.⁵⁵ Because the esophagus contains a rich network of interconnecting lymphatic channels, lymphatic spread from esophageal cancer is unpredictable, with jump metastases to lymph nodes in the neck or mediastinum often occurring in the absence of segmental lymph node involvement.^{55,56} Submucosal esophageal lymphatics also communicate subdiaphragmatically with paracardiac, lesser curvature, and celiac nodes in the upper abdomen; these nodal groups are involved by tumor in 25% to 50% of patients with esophageal cancer.^{55,56} Although tumors in the distal esophagus are more likely to metastasize to the abdomen, lymphatic spread of cancers in the upper or midesophagus can also result in metastases to celiac or other abdominal lymph nodes.⁵⁵

Discrete lymphatic metastases or satellite nodules are found in the esophagus at autopsy in about 50% of patients with esophageal cancer.⁵⁵ These lesions should be distinguished pathologically from rare double primary carcinomas of the esophagus.^{57,58} However, it may be impossible to determine whether two discrete lesions represent synchronous primary tumors or a single cancer with lymphatic dissemination.

Between 2% and 15% of patients dying of esophageal cancer have gastric metastases at autopsy.⁵⁹ These lesions probably result from tumor emboli that seed the gastric fundus via submucosal esophageal lymphatics extending subdiaphragmatically to the stomach.^{59,60} In such cases, the primary esophageal cancer may be located a considerable distance from the gastroesophageal junction, with a normal esophageal segment below the lesion.

Hematogenous Metastases

Hematogenous (bloodborne) metastases are often found in patients with advanced esophageal carcinoma. The most common sites of metastases are the lungs, liver, adrenals, kidneys, pancreas, peritoneum, and bones.

CLINICAL ASPECTS

Most patients with esophageal cancer develop dysphagia only when the lumen of the esophagus has been reduced by 50% to 75% of its normal size.^{48,50} By that time, malignant invasion of periesophageal lymph nodes or surrounding mediastinal structures has usually occurred.⁴⁸ As a result, most patients have advanced, unresectable tumors at the time of diagnosis. Occasionally, however, patients experience dysphagia while the tumor is at an early stage.^{46,61-63} It is therefore possible to detect early esophageal cancer in some patients who are symptomatic.

Dysphagia is the most common complaint in patients with advanced esophageal cancer.⁴⁸ Dysphagia is usually present for 2 to 4 months before these patients seek medical attention.⁴⁸ Some patients can accurately localize the level of obstruction, but others may have a sensation of blockage referred to the thoracic inlet or even the pharynx by a cancer arising in the middle or lower thoracic esophagus.⁵⁰ The esophagus should therefore be carefully evaluated in all patients with unexplained pharyngeal dysphagia to rule out an esophageal cancer below the subjective site of obstruction.

Patients with esophageal cancer may also present with odynophagia if the tumor is ulcerated or with substernal chest pain unrelated to swallowing if the tumor has invaded the mediastinum, so unremitting chest pain is an extremely poor prognostic sign.⁵⁰ Other common symptoms include anorexia and weight loss, which are present in up to 75% of cases.² Some patients may present with guaiac-positive stool or iron deficiency anemia as a result of occult bleeding from the friable surface of the tumor.⁴⁸ However, frank hematemesis is uncommon.^{64,65} Rarely, fatal hemorrhage may be caused by an aorto-esophageal fistula.^{66,67} The latter patients may have minimal hematemesis before the sudden development of massive hemorrhage, shock, and death.

Other patients with esophageal cancer may develop hoarseness because of direct extension of tumor into the larynx or involvement of the recurrent laryngeal nerve.⁴⁸ Recurrent aspiration may lead to a chronic cough. However, the presence of a paroxysmal cough on swallowing should suggest the development of a malignant tracheoesophageal or esophagobronchial fistula. Rarely, patients with esophageal cancer may have anorexia, weight loss, or other signs of widespread malignancy without experiencing dysphagia, so localizing esophageal symptoms are not always present.⁵⁰

ENDOSCOPIC FINDINGS

When multiple biopsy specimens are obtained, endoscopy has an overall sensitivity of almost 100% in the diagnosis of esophageal carcinoma.^{2,68,69} Brush cytology is also helpful when the esophageal lumen is so compromised by tumor that adequate biopsy specimens cannot be obtained. Detection of suspicious lesions on barium studies should therefore lead to early endoscopy and biopsy for a definitive diagnosis.

RADIOGRAPHIC FINDINGS

Early Esophageal Cancer

Double-contrast esophagography has been widely advocated as the best radiologic technique for diagnosing early esophageal cancer. Unfortunately, the increased sensitivity of this technique has resulted in a lower specificity because more

subtle abnormalities are suspected of representing cancer.⁴⁶ Nevertheless, it is probably best to accept a certain percentage of false-positive findings to avoid missing early tumors. When a lesion is detected on barium studies, endoscopy and biopsy should therefore be performed to confirm the presence of carcinoma.

Early esophageal cancers classically appear on double-contrast esophagograms as small protruded lesions less than 3.5 cm in diameter.^{46,61,63,70,71} They may be plaque-like lesions, often with central ulceration (Fig. 23-1), or small sessile polyps with a smooth or slightly lobulated contour (Fig. 23-2). Other early cancers may be superficial or depressed lesions, causing focal irregularity, nodularity, or ulceration of the mucosa (Fig. 23-3).⁷²⁻⁷⁴ When a lesion is detected on double-contrast studies, multiple projections should be obtained to determine its appearance en face and in profile (see Fig. 23-1).

Although most early esophageal cancers appear as focal lesions, superficial spreading carcinomas may be manifested by poorly defined nodules or plaques, producing a confluent area of mucosal nodularity or granularity (Fig. 23-4).^{63,72-75} Some superficial spreading carcinomas may be localized lesions, whereas others may involve a considerable segment of the esophagus.

Early esophageal cancers are generally thought to be small lesions, but some early cancers may appear on barium studies as relatively large intraluminal mass larger than 3.5 cm in diameter (Fig. 23-5).^{63,76} Such lesions may be indistinguishable from advanced carcinomas. Thus, early esophageal cancers are not

Figure 23-1 Early esophageal cancer. **A.** En face view from a double-contrast esophagogram shows a poorly defined lesion (arrows) in the midesophagus. **B.** However, a tangential view reveals a characteristic plaque-like lesion containing a flat area of central ulceration (arrow). (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 23-2 Early esophageal cancer. The lesion appears radiographically as a small sessile polyp (arrow) in the midesophagus. A benign squamous papilloma could produce a similar appearance. (Courtesy Seth N. Glick, MD, Philadelphia.)

Figure 23-3 Two examples of early esophageal cancer. A, B. In both cases there is focal irregularity and puckering of one wall of the esophagus (arrows) without a discrete mass. (A courtesy Akiyoshi Yamada, MD, Tokyo.)

Figure 23-4 Superficial spreading carcinoma. A, B. There is focal nodularity in the midesophagus as a result of poorly defined nodules and plaques, producing a confluent area of disease. B. In another patient with a more extensive lesion, there is diffuse granularity of the mucosa. (A from Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 23-5 Early esophageal cancer. This lesion appears as a relatively large polypoid mass indistinguishable from an advanced carcinoma. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

necessarily small cancers because they may undergo considerable intraluminal or intramural growth and still be classified histologically as early lesions.

Advanced Carcinoma

Chest Radiography. Almost 50% of patients with advanced esophageal cancers have abnormal chest radiographs.⁷⁷ The most common findings include mediastinal widening, a hilar, retrohilar, or retrocardiac mass, anterior tracheal bowing, a widened retrotracheal stripe, and an air-fluid level in the esophagus (Fig. 23-6).⁷⁷⁻⁷⁹ Anterior bowing of the trachea or thickening of the retrotracheal stripe beyond 3 mm in width may result from lymphatic infiltration or direct invasion of the retrotracheal area by tumor.^{78,79} Obstructing cancers may be recognized by an air-fluid level in the esophagus. However, esophageal obstruction from achalasia or other causes may also be manifested by anterior tracheal bowing or an esophageal air-fluid level.

Barium Studies. Double-contrast esophagography is often performed on patients with dysphagia to rule out carcinoma or other abnormalities in the esophagus. Some gastroenterologists believe that endoscopy is required for all patients with negative esophagograms to find tumors that are missed on barium studies. In a large series of patients with esophageal cancer, however, the lesion was detected on double-contrast esophagograms in 98% of cases, and malignant tumor was diagnosed or suspected on the basis of the radiographic findings in 96%.⁸⁰ An argument could be made that a high sensitivity is achieved in the radiographic diagnosis of esophageal cancer only by exposing an inordinate number of patients to unnecessary endoscopy. In the previous study, however, endoscopy was recommended to rule out malignant tumor in only about 1% of

all patients who underwent double-contrast examinations.⁸⁰ Similarly, in other series, endoscopy has failed to reveal any cases of esophageal carcinoma that were missed on double-contrast esophagograms.^{81,82} Thus, endoscopy is not routinely warranted for patients who have normal findings on barium studies.

Advanced esophageal carcinomas may appear on barium studies as infiltrating, polypoid, ulcerative, or varicoid lesions (Fig. 23-7).⁸³⁻⁸⁶ However, many esophageal cancers have mixed morphologic features, so there is considerable overlap in the classification of these tumors.

Infiltrating esophageal carcinomas are characterized by irregular narrowing and constriction of the lumen associated with a nodular or ulcerated mucosa and abrupt, well-defined proximal and distal margins (see Fig. 23-7A). Occasionally, these cancers have shelflike, overhanging margins, producing true annular lesions (Fig. 23-8A).⁸³ However, other infiltrating lesions have more gradual, tapered margins, occasionally mimicking the appearance of benign strictures (Fig. 23-8B).⁸⁴ Infiltrating lesions may eventually cause partial or even complete esophageal obstruction, with proximal dilation and minimal or no emptying of barium into the stomach.

Polypoid carcinomas appear as lobulated or fungating intraluminal masses, usually larger than 3.5 cm (see Fig. 23-7B).⁸³⁻⁸⁵ They often contain areas of ulceration caused by tumor necrosis. Bulky lesions may eventually cause luminal encroachment and obstruction. However, squamous cell carcinomas are not generally polypoid, so other malignant tumors such as spindle cell carcinoma should be considered in these patients (see Chapter 24).

Primary ulcerative carcinomas are those in which the bulk of the tumor mass is replaced by ulceration. When viewed in profile, these lesions appear as well-defined meniscoid ulcers,

Figure 23-6 Advanced esophageal carcinoma with abnormal chest radiographs. **A.** Posteroanterior chest radiograph shows widening of the superior mediastinum on the right (arrows). **B.** Lateral radiograph shows increased soft-tissue density in the retrotracheal space with slight anterior bowing of the trachea (straight arrow) by an advanced esophageal cancer in this region. Also note thickening of the retrotracheal stripe inferiorly (curved arrow) caused by direct invasion of this area by tumor. (Courtesy Wallace T. Miller, MD, Philadelphia.)

Figure 23-7 Advanced esophageal carcinoma: patterns of tumor. **A.** Infiltrating lesion. **B.** Polypoid lesion. **C.** Ulcerative lesion with a large, meniscoid ulcer (arrows) surrounded by a thick radiolucent rim of tumor. **D.** Varicoid lesion with thickened tortuous folds in the midesophagus caused by submucosal spread of tumor. (**A-C** from Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989; **D** courtesy Akiyoshi Yamada, MD, Tokyo.)

with a thick, irregular, radiolucent rim of tumor surrounding the ulcer (see Fig. 23-7C).^{85,87}

Varicoid carcinomas are those in which submucosal spread of tumor results in thickened, tortuous, or serpiginous longitudinal folds, mimicking the appearance of esophageal varices (see Fig. 23-7D).⁸⁸⁻⁹⁰ However, these entities can usually be differentiated at fluoroscopy (see later, “Differential Diagnosis”). Although varicoid carcinomas are uncommon, submucosal extension of tumor not infrequently produces a focal varicoid pattern adjacent to an obvious squamous cell carcinoma. In one study, a varicoid pattern was seen on esophagography in 40% of patients with esophageal cancer.⁹¹

Mediastinal involvement by advanced esophageal carcinoma can also be recognized on barium studies. Lymphatic spread of tumor to paratracheal, subcarinal, or paraesophageal lymph nodes may lead to extrinsic compression or displacement of the esophagus, often at a considerable distance from the primary lesion (Fig. 23-9). Mediastinal lymphadenopathy is usually characterized by a smooth, extrinsic esophageal impression with gently sloping, obtuse borders. This finding almost always indicates an advanced, unresectable lesion.

Lymphatic metastases from esophageal cancer may be manifested by discrete implants adjacent to or remote from the primary lesion. These metastases may appear on barium studies as small plaque-like, polypoid, submucosal, or ulcerated lesions

separated from the main tumor by normal intervening mucosa (Fig. 23-10).⁹² Although most of these satellite lesions represent lymphatic metastases from the original cancer, the possibility of two primary carcinomas (double primaries) should be considered when the lesions are separated by an unusually long segment of normal mucosa.⁵⁷

Squamous cell metastases to the stomach usually appear on barium studies as solitary, large submucosal masses in the gastric fundus.^{59,60} These lesions often contain areas of ulceration, so they may resemble ulcerated gastrointestinal stromal tumors (GISTs; Fig. 23-11). Less frequently, they can be mistaken for primary gastric carcinomas.⁹³ Because the appropriate treatment for esophageal cancer depends on the stage of the tumor, the gastric cardia and fundus should be carefully examined radiographically in all patients with esophageal cancer to rule out unsuspected metastases to the stomach.

Five percent to 10% of patients with esophageal cancer develop an esophageal-airway fistula (Fig. 23-12).^{51,52} This complication frequently occurs after radiation therapy, probably as a result of radiation-induced tumor necrosis. Most such fistulas involve the trachea or left main bronchus.⁵² Occasionally, however, a locally aggressive esophageal cancer may lead to the development of a necrotic, tumor-containing cavity in the mediastinum or lung that communicates directly with the

Figure 23-8 Other forms of infiltrative esophageal carcinoma.

A. This lesion has an annular appearance, with shelflike proximal and distal margins. **B.** In another patient, the cancer is manifested by a relatively smooth, tapered area of narrowing that could be mistaken for a benign stricture. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 23-9 Advanced esophageal carcinoma with mediastinal adenopathy.

There is a smooth extrinsic area of mass effect on the left lateral wall of the upper thoracic esophagus (arrows) by mediastinal adenopathy from a distal esophageal cancer (not shown on this image). (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

esophagus (Fig. 23-13). When an esophageal-airway fistula is suspected, the esophagogram should be performed with barium rather than water-soluble contrast agents because the latter agents are hyperosmolar and may draw fluid into the lungs if a fistula is present, causing severe pulmonary edema.

Esophageal-airway fistulas are usually recognized on esophagography by the presence of barium in the bronchi or distal trachea. In many cases, the origin of the fistulous track is identified within an obvious infiltrating carcinoma (see Fig. 23-12B). Once barium has entered the trachea or left main bronchus, however, it can be coughed up into the proximal trachea or larynx, so delayed overhead radiographs may erroneously suggest tracheobronchial aspiration. When an esophageal-airway fistula is suspected, the initial swallow should therefore be performed in a lateral projection with a video recording of the hypopharynx to differentiate a fistula from aspiration.

Rarely, patients with advanced esophageal cancer may develop esophagopericardial fistulas, manifested by pneumopericardium on chest radiographs or computed tomography (CT) scans.⁵⁴ In such cases, esophagography with water-soluble contrast agents may demonstrate esophageal perforation at the site of the tumor, with contrast material entering the pericardial sac.

Associated Conditions

Achalasia. Esophageal carcinomas arising in patients with achalasia usually appear on barium studies as polypoid masses

in the middle or, less commonly, distal third of the esophagus (Fig. 23-14).^{17,21} Because these lesions often develop in a massively dilated esophagus, they can reach an enormous size, producing bulky intraluminal masses that have a fungating or cauliflower appearance.²¹ Nevertheless, the lesions may be obscured by retained fluid and debris in a dilated, partially obstructed esophagus.¹⁹⁻²¹ Careful esophageal lavage with a soft rubber catheter may therefore be required to cleanse the esophagus before performing the radiologic examination.

Lye Strictures. The development of a lye-induced cancer may be manifested on barium studies by increasing stenosis, mass effect, nodularity, and/or ulceration within a preexisting lye stricture (Fig. 23-15). The underlying strictures are often located in the region of the tracheal bifurcation, so lye cancers may be complicated by the development of tracheoesophageal or esophagobronchial fistulas (see Fig. 23-15B).²⁵ Any change in the appearance of a chronic lye stricture should therefore be evaluated by endoscopy with multiple biopsy specimens and brushings to rule out a superimposed carcinoma.

Tylosis. When patients with tylosis develop esophageal symptoms, they usually have advanced esophageal carcinomas, manifested on barium studies by annular, infiltrating, or plaque-like lesions.⁴⁰ Occasionally, however, asymptomatic patients with tylosis may have discrete hyperkeratotic plaques containing one or more foci of dysplasia or intramucosal carcinoma. These

Figure 23-10 Two examples of advanced esophageal carcinoma with discrete lymphatic metastases. **A.** This patient has a large ulcerated cancer (*large arrows*) in the midesophagus with a discrete metastatic implant (*small arrow*) separated from the main lesion by normal intervening mucosa. The implant appears as a plaque-like lesion. **B.** In another patient, a polypoid carcinoma (*curved arrows*) is present in the midesophagus with a discrete submucosal implant (*straight arrow*) more proximally.

Figure 23-11 Advanced esophageal carcinoma with a squamous cell metastasis to the stomach. There is a giant submucosal mass (*black arrows*) in the gastric fundus, containing a triangular area of central ulceration (*white arrows*). A malignant gastrointestinal stromal tumor could produce similar findings. (From Glick SN, Teplick SK, Levine MS: *Squamous cell metastases to the gastric cardia*. *Gastrointest Radiol* 10:339–344, 1985.)

Figure 23-12 Advanced esophageal carcinoma with a tracheoesophageal fistula. **A.** An ulcerative esophageal carcinoma (*arrows*) is present in the midesophagus. **B.** A second esophagogram 4 months after radiation therapy shows partial regression of the tumor with the development of a tracheoesophageal fistula (*arrow*). (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

lesions may appear on esophagograms as large, well-defined plaques, with normal intervening mucosa (Fig. 23-16).⁴⁰

Adenocarcinoma

Primary esophageal adenocarcinomas are almost always found to arise in the setting of Barrett's esophagus. In the past, such tumors were thought to be rare lesions, accounting for less than 5% of all esophageal cancers.⁹⁴⁻⁹⁶ However, many of these adenocarcinomas involving the gastroesophageal junction or gastric fundus were incorrectly classified as primary gastric carcinomas secondarily invading the lower end of the esophagus.^{94,95} Apart from difficulties in tumor classification, the incidence of esophageal adenocarcinoma in white men has increased by 300% to 500% in the past 30 years,^{41,97,98} and this tumor is the fastest growing cause of cancer mortality.⁹⁹ Currently, adenocarcinomas are thought to constitute at least 50% of all esophageal cancers.⁴¹ Nevertheless, many questions remain about the risk of malignant degeneration in Barrett's esophagus and the long-term management of patients with this condition.

EPIDEMIOLOGY AND PATHOGENESIS

Considerable attention has been focused on the relationship between esophageal adenocarcinoma and the columnar

Figure 23-13 Two examples of advanced esophageal carcinoma with fistulas to the mediastinum and lung. In both cases, there is direct communication between the cancer and necrotic, tumor-containing cavities (arrows) in the mediastinum (**A**) and right lung (**B**). (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

epithelium-lined esophagus, or Barrett's esophagus. In various studies, 90% to 100% of all primary esophageal adenocarcinomas have been found to arise on a background of Barrett's mucosa.¹⁰⁰⁻¹⁰² Thus, adenocarcinoma of the esophagus is not only more common than was previously recognized, but the vast majority of these tumors appear to result from malignant degeneration in Barrett's esophagus.

Barrett's Esophagus

Barrett's esophagus is a well-recognized condition in which there is progressive columnar metaplasia of the distal esophagus caused by long-standing gastroesophageal reflux and reflux esophagitis.¹⁰²⁻¹⁰⁶ In various studies, the prevalence of Barrett's esophagus in patients with reflux esophagitis has ranged from 5% to 15%, with an overall prevalence of about 10%.¹⁰⁷⁻¹⁰⁹ In a widely quoted study, Barrett's esophagus was found to occur in 4% of patients undergoing upper gastrointestinal endoscopy and in 9% of men older than 50 years.¹¹⁰ The clinical and radiologic aspects of Barrett's esophagus are presented in Chapter 19.

Various types of columnar epithelium have been described in Barrett's esophagus, including a junctional-type epithelium, a gastric fundus-type epithelium, and an intestinal-type or specialized columnar epithelium.^{111,112} It is believed, however, that intestinal metaplasia is the major prerequisite for a pathologic diagnosis of Barrett's esophagus.¹¹³ This intestinal metaplasia is characterized histologically by goblet cells with acidic mucin and, in some cases, enterocyte differentiation with brush border formation. The revised definition of Barrett's esophagus is based on an emerging consensus that intestinal metaplasia represents the type of epithelium that usually predisposes these patients to the development of esophageal adenocarcinoma.^{113,114}

Figure 23-14 Advanced esophageal carcinoma associated with achalasia. There is a large, fungating mass in the lower esophagus in a patient with long-standing achalasia. Note beaklike narrowing (arrow) of the distal esophagus caused by incomplete opening of the lower esophageal sphincter. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 23-15 Advanced esophageal carcinoma arising in a lye stricture. **A.** Initial double-contrast esophagogram shows a focal stricture (arrow) in the midesophagus caused by previous lye ingestion. Note superficial ulceration and nodularity of the mucosa in the region of the stricture. These findings were worrisome for developing tumor, but the patient refused endoscopy. **B.** Another study 2 years later shows an advanced, infiltrating carcinoma at the site of the previous stricture, with an esophagobronchial fistula (arrow). (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Investigators have also developed histopathologic criteria for Barrett's esophagus in which patients are classified as having long-segment disease (i.e., extending more than 3 cm from the gastroesophageal junction) or short-segment disease (i.e., extending 3 cm or less from the gastroesophageal junction) based on the vertical extent of columnar metaplasia in the esophagus.¹¹⁵ Short-segment Barrett's esophagus is even more common than long-segment Barrett's esophagus, with a reported prevalence of 10% to 15% at endoscopy.¹¹⁴

Risk of Adenocarcinoma. In various series, the prevalence of adenocarcinoma in patients with Barrett's esophagus has ranged from 2% to 46%, with an overall prevalence of about 10%.^{*}

It should be recognized that prevalence data exaggerate the risk of cancer because many patients with Barrett's esophagus remain asymptomatic until the development of a superimposed carcinoma. Nevertheless, it has been estimated that patients with Barrett's esophagus have at least a 20-fold increased risk of developing esophageal adenocarcinoma.^{118,119} Current surveillance guidelines for Barrett's esophagus assume that the absolute annual risk of developing cancer is about 0.5%, but

Figure 23-16 Tylosis with hyperkeratotic plaques. There are multiple discrete plaques (arrows) in the mid and distal esophagus. These lesions were found to be hyperkeratotic plaques in a patient with long-standing tylosis. (From Munyer TP, Margulis AR: Tylosis. *AJR* 136:1026–1027, 1981.)

one large study found that the actual risk was only 0.12%, calling into question the rationale for ongoing surveillance of asymptomatic patients who have Barrett's esophagus without associated dysplasia (see later, "Surveillance and Management of Barrett's Esophagus").¹²⁰

Dysplasia-Carcinoma Sequence. Pathologic data strongly suggest that esophageal adenocarcinoma in Barrett's esophagus evolves through a sequence of progressively severe epithelial dysplasia in areas of preexisting columnar metaplasia, usually intestinal metaplasia.^{121–124} These dysplastic changes can be detected on endoscopic biopsy specimens obtained from Barrett's esophagus. Dysplasia may occur in all types of Barrett's mucosa but is most likely to occur in areas of intestinal metaplasia.^{113,114} Dysplastic changes are classified as low grade or high grade on the basis of the histologic findings; high-grade dysplasia may subsequently progress to invasive adenocarcinoma. In various studies, the prevalence of high-grade dysplasia in patients with esophageal adenocarcinoma has ranged from 68% to 100%.^{105,116} Studies have also shown progression to cancer within 7 years in 22% of patients with high-grade dysplasia in Barrett's esophagus.²

When Barrett's esophagus is stratified into short-segment and long-segment disease, it has been found that patients with short-segment disease are more likely to develop dysplasia than the general population but are less likely to develop dysplasia than patients with long-segment disease.^{125,126} Esophageal adenocarcinoma has also been found to develop in patients with

*See references 101, 105, 107, 108, 116, and 117.

short-segment disease.^{125,127,128} Additional studies are needed, however, to further elucidate the cancer risk in these patients.

Surveillance and Management of Barrett's Esophagus.

Because of the increased cancer risk, many investigators advocate endoscopic surveillance of patients with known Barrett's esophagus to detect dysplastic changes, so these individuals can be treated before the development of overt carcinoma.^{2,100,103-105,121-123} Endoscopic biopsy specimens are generally recommended from all four quadrants of the lower esophagus at 1- to 2-cm intervals, starting at the gastroesophageal junction.² In patients with nondysplastic Barrett's esophagus, the American Gastroenterological Association recommends surveillance endoscopy at 2- to 5-year intervals, depending on the patient's age and health.¹²⁴ In patients with low-grade dysplasia, endoscopy is recommended at 1- to 2-year intervals because of an increased but uncertain risk of developing cancer.² If high-grade dysplasia or early cancer is detected, treatment should be undertaken to prevent the development of cancer or treat these cancers at a curable stage. In the past, a surgical esophagogastrectomy was the definitive treatment for high-grade dysplasia or early cancers in Barrett's esophagus. Currently, however, various forms of endoscopic therapy are recommended as less invasive alternatives associated with lower morbidity and mortality rates than surgery.⁹⁹ Radiofrequency ablation, photodynamic therapy, and endoscopic mucosal resection have all been shown to be effective and safe forms of therapy for treatment of high-grade dysplasia or early-stage cancer in Barrett's esophagus, with a high rate of dysplasia and tumor eradication and a reduced risk of disease progression in these patients.¹²⁹⁻¹³¹

Despite these recommendations, there is continued controversy about whether endoscopic surveillance of patients with Barrett's esophagus is a cost-effective approach for detecting esophageal adenocarcinoma because of the low incidence of neoplasia and the high cost of endoscopy.¹¹⁸ So far, endoscopic surveillance of patients with Barrett's esophagus has not been associated with a substantially decreased risk of death from esophageal adenocarcinoma.¹³² Thus, many questions remain about the role of endoscopic surveillance and its ultimate value in patients with Barrett's esophagus.

Attention has also been focused on the role of DNA flow cytometry and cellular genetics analysis to determine which patients with Barrett's esophagus are at greatest risk for the development of adenocarcinoma. Some investigators have shown that a subset of patients with Barrett's esophagus have genomic instability, with aneuploid populations of cells, predisposing to neoplastic transformation.¹³³ In various studies, the findings on DNA flow cytometry have correlated directly with the presence of high-grade dysplasia or invasive carcinoma on endoscopic biopsy specimens.^{133,134} Thus, flow cytometry represents another potential diagnostic tool for surveillance of Barrett's esophagus.

Much less frequently, the development of cancer in Barrett's esophagus may result from an adenoma-carcinoma sequence similar to that found in the colon. Benign adenomatous polyps have occasionally been documented in Barrett's mucosa, with or without focal areas of invasive adenocarcinoma.^{101,135,136} Because malignant degeneration of these adenomas represents another potential pathway for the development of adenocarcinoma, endoscopic resection of adenomatous polyps in Barrett's esophagus may decrease the risk of cancer.

Relationship Among Scleroderma, Barrett's Esophagus, and Adenocarcinoma.

Scleroderma, a connective tissue disease characterized by smooth muscle atrophy and fibrosis, affects the esophagus in about 75% of patients. Esophageal involvement is usually characterized by a patulous, incompetent lower esophageal sphincter and absent esophageal peristalsis, with poor clearance of refluxed peptic acid from the esophagus once reflux has occurred. As a result, patients with scleroderma often have reflux esophagitis. Because of the severity of esophagitis, these individuals have an even greater risk of developing Barrett's esophagus than other patients with reflux disease. In one study, 37% of those with scleroderma who underwent endoscopy for reflux symptoms had biopsy-proven Barrett's esophagus.¹³⁷ Because Barrett's esophagus predisposes to esophageal adenocarcinoma, patients with scleroderma also appear to have an increased risk of developing esophageal cancer.^{137,138} Thus, scleroderma should indirectly be considered to be a premalignant condition in the esophagus.

PATHOLOGY

Gross Features

Adenocarcinomas arising in Barrett's mucosa appear grossly as infiltrating, polypoid, ulcerative, or varicoid lesions. These tumors tend to be located in the distal or, less commonly, middle third of the esophagus.^{101,102,139} Unlike squamous cell carcinomas, adenocarcinomas of the distal esophagus frequently spread subdiaphragmatically to involve the gastric cardia or fundus.^{101,102,112,139} Studies have shown that adenocarcinomas arising in Barrett's esophagus account for up to 50% of all adenocarcinomas involving the gastroesophageal junction.^{101,102,139} The remaining lesions are primary carcinomas of the gastric cardia or fundus invading the esophagus. Whether they arise in the esophagus or in the stomach, these tumors have similar morphologic features in terms of pattern of growth, degree of differentiation, and depth of invasion.¹⁴⁰ Nevertheless, it is important to ascertain whether the cancer has arisen in Barrett's esophagus because it may be necessary to resect not only the primary tumor but all residual Barrett's mucosa in these patients. Detection of malignant tumor at the cardia should therefore lead to a careful search for Barrett's epithelium in the esophagus.

Histologic Features

At the time of diagnosis, most adenocarcinomas in Barrett's esophagus are advanced, unresectable tumors. Occasionally, however, early, potentially curable lesions may be detected by radiologic or endoscopic surveillance of patients with known Barrett's esophagus. Alternatively, early lesions may be detected fortuitously in patients who undergo barium studies or endoscopy because of their underlying reflux disease.^{63,123,141}

ROUTES OF SPREAD

Like squamous cell carcinomas, esophageal adenocarcinomas invade local, regional, or distant structures via direct extension, lymphatic spread, or hematogenous metastases. Unlike squamous cell carcinomas, however, adenocarcinomas in Barrett's esophagus have a marked tendency to invade the proximal stomach; involvement of the gastric cardia or fundus occurs in 35% to 50% of cases.^{101,102,139}

CLINICAL ASPECTS

Barrett's esophagus is predominantly a disease of older white men, with a male-to-female ratio of 3:1 and a mean age of about 65 years at the time of diagnosis. Nevertheless, there has been a significant increase in the incidence of these tumors in younger patients between 45 and 65 years of age.²

Patients with esophageal adenocarcinoma usually present with recent onset of dysphagia and weight loss.^{104,105,116,120} Other findings include upper GI bleeding, odynophagia, and chest pain.¹¹⁶ Because of their underlying reflux disease, some patients have long-standing reflux symptoms before the development of cancer.¹⁰⁴ By the time these individuals develop dysphagia, however, they almost always have advanced, unresectable tumors. Thus, patients with esophageal adenocarcinomas have a poor prognosis, with overall 5-year survival rates less than 20%.^{2,142}

Most patients with early adenocarcinomas in Barrett's esophagus are asymptomatic, but some may present with melena, guaiac-positive stool, or iron deficiency anemia as a result of low-grade bleeding from the friable surface of the tumor.⁶³ Others may seek medical attention because of their underlying reflux disease, so early cancers may be detected as fortuitous findings in patients presenting with reflux symptoms.⁶³

RADIOGRAPHIC FINDINGS

Early Adenocarcinoma

Like squamous cell carcinomas, early adenocarcinomas in Barrett's esophagus may appear on double-contrast esophagograms as plaquelike lesions or as flat sessile polyps.⁶³ Sessile or pedunculated polyps in the distal esophagus may also represent adenomatous polyps in Barrett's mucosa with or without foci of invasive carcinoma (Fig. 23-17).^{101,136} In patients with peptic strictures, the earliest manifestation of a developing adenocarcinoma may be a localized area of flattening, stiffening, or irregularity in one wall of the stricture (Fig. 23-18).^{63,101,102} Other patients may have superficial spreading carcinomas, manifested by confluent nodularity or granularity of the mucosa without a discrete lesion.⁶³ Although early adenocarcinomas are typically small lesions, some patients may have relatively larger polypoid masses that are indistinguishable radiographically from advanced cancers.⁶³

Advanced Adenocarcinoma

Advanced esophageal adenocarcinomas usually appear on barium studies as infiltrating lesions with irregular luminal narrowing, nodularity or ulceration of the mucosa, and abrupt, asymmetric margins (Fig. 23-19A).^{101,102,139} In general, these lesions cannot be distinguished radiographically from squamous cell carcinomas. In one study, however, esophageal adenocarcinomas were found to involve a longer vertical segment of the esophagus than squamous cell carcinomas.¹⁰² Adenocarcinomas are also more likely to involve the distal esophagus,¹⁰¹ so the presence of a long infiltrating lesion in the distal esophagus should suggest the possibility of adenocarcinoma.

Less frequently, these tumors may appear as polypoid intraluminal masses (Fig. 23-19B) or as primary ulcerative lesions, with a meniscoid ulcer surrounded by a thick rind of tumor (Fig. 23-19C).^{101,102} Occasionally, these lesions may have a varicoid appearance caused by submucosal spread of tumor

Figure 23-17 Early adenocarcinoma in Barrett's esophagus.

There is a large pedunculated polyp (arrows) in the distal esophagus. Pathologic examination of the resected specimen revealed an adenomatous polyp with a solitary focus of adenocarcinoma. (From Levine MS, Caroline D, Thompson JJ, et al: *Adenocarcinoma of the esophagus: Relationship to Barrett mucosa*. Radiology 150:305–309, 1984.)

(Fig. 23-19D).^{101,102,143} Similar findings may be present in patients with squamous cell carcinomas. However, many patients with adenocarcinomas arising in Barrett's esophagus have associated hiatal hernias, gastroesophageal reflux, reflux esophagitis, or peptic strictures.^{101,102} The possibility of adenocarcinoma should therefore be considered in any patient with esophageal cancer who has other clinical or radiologic signs of reflux disease.

When adenocarcinomas are located in the distal esophagus, they have a marked tendency to invade the gastric cardia or fundus.^{101,102,139} Gastric involvement may be manifested on barium studies by a polypoid or ulcerated mass in the fundus. In other patients, these tumors may cause distortion or obliteration of the normal anatomic landmarks at the cardia and irregular areas of ulceration without a discrete mass (Fig. 23-20).¹⁰¹ The findings may be quite subtle, so optimal double-contrast views of the gastric cardia and fundus are required to demonstrate these lesions. In general, esophageal adenocarcinomas invading the gastric cardia or fundus are difficult to differentiate radiographically from carcinomas of the cardia or fundus invading the distal esophagus. However, esophageal adenocarcinomas usually have a greater degree of esophageal involvement in relation to that of the stomach, whereas cardiac carcinomas have a greater degree of fundal involvement.

Figure 23-18 Early adenocarcinoma in Barrett's esophagus.

There is a relatively long peptic stricture in the distal esophagus with slight flattening and stiffening of one wall of the stricture (arrows). Surgery revealed an intramucosal adenocarcinoma arising in Barrett's esophagus. (From Levine MS, Caroline D, Thompson JJ, et al: Adenocarcinoma of the esophagus: Relationship to Barrett mucosa. *Radiology* 150:305–309, 1984.)

Differential Diagnosis

EARLY ESOPHAGEAL CANCER

Early squamous cell carcinomas and adenocarcinomas usually appear on double-contrast esophagograms as plaquelike lesions or as flat sessile polyps. However, squamous papillomas may also appear as small, sessile, slightly lobulated polyps that are indistinguishable from early esophageal cancers (see Chapter 22).¹⁴⁴ *Candida* esophagitis and glycogenic acanthosis usually produce multiple plaquelike defects in the esophagus, but a single large plaque can be mistaken for a plaquelike carcinoma. Occasionally, inflammatory exudates or pseudomembranes associated with severe reflux esophagitis may also appear radiographically as plaquelike defects indistinguishable from early adenocarcinomas (Fig. 23-21).¹⁴⁵ However, pseudomembrane formation may be suggested by the presence of other discrete satellite lesions or by a change in the size and appearance of the lesions at fluoroscopy. When the radiographic findings are equivocal, endoscopy and biopsy are required for a definitive diagnosis.

Because superficial spreading carcinomas are manifested on double-contrast esophagograms by tiny nodules or plaques, a localized area of *Candida* esophagitis could conceivably produce a similar appearance (Fig. 23-22).¹⁴⁶ However, the plaquelike

defects of candidiasis tend to be discrete lesions with well-defined borders and normal intervening mucosa, whereas the nodules or plaques of superficial spreading carcinoma tend to coalesce, producing a continuous area of disease. Superficial spreading carcinomas that are more extensive should be differentiated from other benign conditions causing a diffusely nodular mucosa, such as *Candida* esophagitis, glycogenic acanthosis or, rarely, leukoplakia, acanthosis nigricans, and squamous papillomatosis.^{146–150} However, the latter conditions also tend to produce discrete lesions rather than a continuous area of disease. Finally, superficial spreading carcinoma may produce a reticulonodular appearance that closely resembles the reticular pattern of Barrett's mucosa.¹⁵¹ However, this last finding is usually associated with a midesophageal stricture, with the reticular pattern extending distally a variable distance from the stricture (see Chapter 19).

ADVANCED CARCINOMA

Infiltrating esophageal carcinomas usually have an obvious malignant appearance. Occasionally, however, these lesions may resemble benign strictures with concentric narrowing and relatively smooth, tapered margins (see Fig. 23-8B).^{84,152} In such cases, an abrupt change in caliber and focal irregularity, nodularity, or stiffening of one or both walls of the stricture should raise the possibility of malignant tumor, particularly an adenocarcinoma in Barrett's esophagus.^{101,102} Rarely, esophageal cancer may cause beaklike narrowing of the distal esophagus, mimicking the appearance of primary achalasia.¹⁰² However, asymmetry, nodularity, or ulceration of the narrowed segment should suggest a malignant lesion.

When infiltrating cancers are detected in the esophagus, it may be difficult or impossible to differentiate squamous cell carcinomas from adenocarcinomas arising in Barrett's mucosa. However, adenocarcinomas tend to be located more distally in the esophagus and often invade the gastric cardia or fundus, whereas squamous cell carcinomas rarely extend subdiaphragmatically to involve the stomach.^{101,102,139} Other clinical or radiographic signs of reflux esophagitis should also favor adenocarcinoma. Nevertheless, endoscopy and biopsy are required for a definitive diagnosis.

Although squamous cell carcinomas and adenocarcinomas sometimes appear as polypoid masses in the esophagus, the presence of a bulky intraluminal mass (especially one that expands the esophagus without causing obstruction) should suggest the possibility of other rare malignant tumors such as spindle cell carcinoma and primary malignant melanoma of the esophagus (see Chapter 24).^{153,154} Rarely, benign tumors such as fibrovascular polyps may be manifested by polypoid lesions, but these tumors tend to appear as smooth, expansile, sausage-shaped masses in the upper thoracic esophagus (see Chapter 22).¹⁵⁵ Finally, impacted food in the esophagus may be confused radiographically with polypoid carcinomas. However, the presence of a stricture directly below the polypoid defect should suggest the possibility of a food impaction. Impacted debris may also obstruct the esophagus, whereas polypoid carcinomas rarely cause esophageal obstruction. Obviously, a history of sudden onset of dysphagia while eating meat or some other bulky food product should suggest this complication.

Primary ulcerative carcinomas usually appear as distinctive meniscoid ulcers surrounded by a thick, irregular rim of malignant tissue. However, the adjacent tumor mass is sometimes

Figure 23-19 Advanced adenocarcinoma in Barrett's esophagus: patterns of tumor. **A.** Infiltrating lesion. **B.** Polypoid lesion (arrows). **C.** Ulcerative lesion (arrow). **D.** Varicoid lesion. (**B** from Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989; **C, D** from Levine MS, Caroline D, Thompson JJ, et al: *Adenocarcinoma of the esophagus: Relationship to Barrett mucosa*. *Radiology* 150:305–309, 1984.)

Figure 23-20 Adenocarcinoma in Barrett's esophagus invading the stomach. Double-contrast view of the gastric fundus shows obliteration of the normal anatomic landmarks at the cardia with irregular areas of ulceration (straight arrows). Also note tumor involving the distal esophagus (curved arrow). At surgery, this patient had a primary adenocarcinoma arising in Barrett's esophagus with associated gastric involvement. (From Levine MS, Caroline D, Thompson JJ, et al: *Adenocarcinoma of the esophagus: Relationship to Barrett mucosa*. *Radiology* 150:305–309, 1984.)

subtle, so these lesions can occasionally be mistaken for benign ulcers. Conversely, some patients with esophagitis may have large, flat ulcers with a surrounding mound of edema, erroneously suggesting an ulcerated carcinoma. Ulcers associated with potassium chloride or quinidine ingestion or nasogastric intubation can have a particularly ominous appearance (see Chapter 21). Endoscopy and biopsy may therefore be required to exclude a malignant lesion.

Although varicoid carcinomas can mimic the appearance of esophageal varices on a single radiograph, these entities can usually be differentiated at fluoroscopy.^{88–90,143} True varices tend to change in size and shape with peristalsis, respiration, and Valsalva maneuvers, whereas varicoid tumors have a rigid, fixed configuration, with an abrupt demarcation between the involved segment and adjacent normal mucosa. Most varicoid carcinomas are squamous cell carcinomas or adenocarcinomas, but other malignant tumors such as lymphoma may occasionally produce similar findings.¹⁵⁶

Rarely, localized submucosal extension of a squamous cell carcinoma or adenocarcinoma may produce a smooth submucosal mass, mimicking the appearance of a benign leiomyoma (Fig. 23-23).¹⁵⁷ However, a malignant tumor should be suspected if there is lobulation or ulceration of the lesion.

Staging

Most authors now recommend CT as the initial imaging test for staging esophageal cancer,^{158,159} and the Society of Thoracic Surgeons has issued guidelines recommending combined CT of the chest and abdomen for optimal staging.¹⁶⁰ Although CT has

Figure 23-21 Reflux esophagitis with a large pseudomembrane, mimicking a plaque-like adenocarcinoma. There is a longitudinally oriented, plaque-like lesion (arrows) on the anterolateral wall of the distal esophagus. The radiographic findings are worrisome for a plaque-like carcinoma, but endoscopy revealed pseudomembranes caused by severe reflux esophagitis without evidence of tumor. (From Levine MS, Cajade AG, Herlinger H, et al: Pseudomembranes in reflux esophagitis. *Radiology* 159:43–45, 1986.)

Figure 23-22 Localized area of *Candida* esophagitis. This appearance could be mistaken for a superficial spreading carcinoma. However, note how the plaques have discrete borders and are separated by short segments of normal mucosa. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

been the mainstay for staging esophageal carcinoma, the increasing use of endoscopic ultrasound (EUS) and positron emission tomography (PET) has altered the staging algorithm for patients with newly diagnosed esophageal cancer. Currently, a combination of CT, EUS, and PET is generally advocated to determine which patients should be treated with surgery versus chemotherapy, combination radiation and chemotherapy, or surgery with neoadjuvant therapy. As with any cancer, staging criteria for esophageal carcinoma include detection of local invasion, regional lymph node involvement, and distant metastases. The different imaging modalities have different strengths and weaknesses for staging esophageal cancer.

COMPUTED TOMOGRAPHY

Technique

When CT is performed for esophageal cancer staging, the scan should include the upper abdomen and thorax because of the high incidence of upper abdominal lymph node metastases at the time of diagnosis.¹⁶¹ Distal esophageal cancers are more likely to be associated with upper abdominal lymph node involvement (Fig. 23-24); the frequency of abdominal lymph node metastases is about 30% for thoracic esophageal cancers above the level of the carina but increases to 70% for cancers below the carina (Fig. 23-25).¹⁶² Because the lymphatic drainage

of the esophagus is longitudinal rather than circumferential (as in the remainder of the GI tract), lymph node metastases tend to occur above and below the site of the primary tumor, often at a considerable distance from the primary lesion rather than immediately adjacent to the tumor (Fig. 23-26). Intravenous contrast material is administered whenever possible to increase detectability of hepatic metastases and better differentiate lymph nodes from vascular structures in the mediastinum. It is controversial whether staging CT should also include the neck to assess for cervical lymph node metastases.

Staging Criteria

The major CT criteria for staging esophageal cancer include detection of (1) local mediastinal invasion, (2) regional lymph node involvement, and (3) distant metastases. CT is better at detecting local invasion of the mediastinum by esophageal cancer than it is at detecting local invasion by other GI cancers, presumably because the mediastinum is a contained space. Thus, direct invasion can be predicted by mass effect criteria that are not useful elsewhere in the GI tract.

The CT criteria for local invasion include the following: (1) loss of the fat plane between the tumor and adjacent structures in the mediastinum; and (2) displacement or indentation of other mediastinal structures. CT findings of displacement of the trachea or bronchus or indentation of the posterior wall of the trachea or bronchus by the tumor mass have been found to be highly accurate for predicting tracheal or bronchial invasion

Figure 23-23 Esophageal carcinoma resembling a benign submucosal mass. However, this lesion (arrows) is larger and has a more irregular contour than most leiomyomas. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

(Figs. 23-27 and 23-28).¹⁶³⁻¹⁶⁵ The combined results from six studies with surgical confirmation revealed that CT had a sensitivity of 93%, specificity of 98%, and accuracy of 97% for predicting tracheobronchial invasion by esophageal cancer.¹⁶⁶

Mass effect criteria can also be used to predict pericardial invasion. If the tumor extends to the posterior surface of the heart with no intervening fat plane, and if the tumor bulges into the lumen of the left atrium on CT or magnetic resonance imaging (MRI), pericardial invasion can be predicted with a high level of confidence (Fig. 23-29). The combined results of those same six studies revealed that CT had a sensitivity, specificity, and accuracy of 94% for predicting pericardial invasion.¹⁶⁶

It is more difficult to predict aortic invasion because the esophagus normally contacts the aorta with no intervening fat plane (Fig. 23-30). Investigators have circumvented this problem by recognizing that the fat plane surrounding the aorta normally has a circumference of 360 degrees, similar to that of a compass. If an esophageal cancer obliterates the fat plane between the esophagus and aorta by more than 25% of the circumference (>90 degrees), tumor is considered to be invading the aorta (Fig. 23-31). If the tumor obliterates less than 45 degrees of the circumference, the aorta is not considered to be invaded by tumor (Fig. 23-32). Finally, if the tumor obliterates 45 to 90 degrees of the circumference, the CT findings are considered to be indeterminate for aortic invasion (Fig. 23-33). By using this criterion, the combined results of those same six

Figure 23-24 Longitudinal lymphatics of esophagus. Lymphatic channels surrounding the distal esophagus drain into paracardiac and lesser curvature lymph nodes in the upper abdomen, accounting for the high frequency of abdominal lymph node metastases in patients with distal esophageal cancers.

studies revealed that CT had a sensitivity of 88%, specificity of 96%, and accuracy of 94% for predicting aortic invasion.¹⁶⁶ CT is currently thought to have an overall accuracy of more than 90% in predicting local invasion and metastases from esophageal cancer.¹⁵⁹

Because lymph node enlargement is the CT criterion used to predict mediastinal or upper abdominal lymph node metastases, CT is limited by the fact that it cannot detect tumor in normal-sized lymph nodes. CT therefore fails to detect nodes that are involved by tumor in the absence of nodal enlargement. Enlarged lymph nodes adjacent to an esophageal cancer also may not be visualized if they are inseparable from the primary lesion. Conversely, when enlarged mediastinal lymph nodes are detected, CT cannot differentiate benign causes of lymph node enlargement from metastatic tumor. In one study, benign enlargement of lymph nodes occurred more frequently when the primary esophageal cancer was large and necrotic.¹⁶⁷ In general, CT has been found to be more accurate for predicting upper abdominal lymph node metastases than mediastinal lymph node metastases.¹⁶⁸

CT of the chest and upper abdomen also enables detection of distant metastases to the lungs, bones, liver, or other structures. These findings are useful for predicting long-term survival in patients with esophageal cancer. In one study, patients with CT findings of mediastinal or subdiaphragmatic invasion by tumor had a significantly shorter survival compared to patients without these findings.¹⁶⁸

Figure 23-25 Relationship between frequency of subdiaphragmatic lymph node metastases and location of esophageal cancer. Distal esophageal cancers have a substantially higher frequency of subdiaphragmatic lymph node metastases than cancers located more proximally in the esophagus.

Figure 23-26 Enlarged subdiaphragmatic lymph node (arrow) as a result of lymphatic metastasis from esophageal carcinoma. Lymphatic metastases may occur at a considerable distance from the primary tumor because of the rich network of longitudinally oriented periesophageal lymphatics.

ENDOSCOPIC ULTRASOUND

Technique

The ultrasound probe is built into the tip of a fiberoptic endoscope designed specifically for EUS. The tip of the probe is covered by a distensible rubber balloon that can be filled with

Figure 23-27 Tracheal invasion by esophageal carcinoma. **A.** CT scan shows esophageal tumor indenting the posterior wall of the trachea. This finding is indicative of tracheal invasion. **B.** Line drawing also shows tracheal invasion by esophageal tumor.

water to provide an acoustic interface between the transducer and esophageal wall. These ultrasound units are stand-alone devices that differ from the upper GI endoscope. The probes are similar in size to standard endoscopes, so they cannot pass through areas of marked luminal narrowing caused by advanced esophageal cancers, preventing adequate staging of these tumors. Reported rates of nontraversability of the tumor at EUS have ranged from 20% to 45%.^{169,170} To circumvent this problem, a tiny probe can be passed through the biopsy channel of a standard endoscope.^{171,172} These probes have the advantage of being able to traverse a greater percentage of esophageal cancers because of the smaller probe caliber. At the same time, these smaller probes use very high-frequency transducers, so they have a more limited field of view.

Figure 23-28 Bronchial invasion by esophageal carcinoma. **A.** CT scan shows esophageal tumor bowing and displacing the posterior wall (arrows) of the left main bronchus. This finding is indicative of bronchial invasion. **B.** Line drawing also shows bronchial invasion by tumor.

Figure 23-29 Pericardial invasion by esophageal carcinoma. **A.** CT scan shows esophageal tumor indenting the posterior wall of the left atrium. This finding is indicative of pericardial invasion. **B.** MRI scan also shows tumor indenting the posterior wall of the left atrium.

Staging Criteria

EUS provides excellent visualization of the five layers of the esophageal wall. These layers are recognized on EUS as alternating layers of increased and decreased echogenicity, producing five rings (Fig. 23-34). The inner echogenic line represents the mucosal interface with the transducer, the central echogenic line represents submucosal fat (fat is echogenic on ultrasound), and the outer echogenic line represents serosal fat. Tumors are usually manifested by hypoechoic masses causing disruption or widening of these esophageal rings (Fig. 23-35). EUS is excellent for detecting esophageal tumors and can often identify lesions that have spread beyond the wall, enabling differentiation of T2 tumors, which are confined to the esophageal wall, from T3 tumors, which extend beyond the esophageal wall into the periesophageal fat. The ability of EUS to detect T4 tumors, which are invading adjacent structures in the mediastinum, is limited by the inability to differentiate invasive tumors

from those that extend to adjacent structures without actual invasion.

A meta-analysis of 13 studies evaluating the accuracy of EUS for esophageal cancer staging has found that EUS has an overall accuracy of 89% for predicting the depth of tumor invasion in the esophageal wall and an accuracy of 79% for predicting mediastinal lymph node metastases (Fig. 23-36).¹⁷³ Many authors therefore believe that EUS should be complementary to helical CT for staging esophageal cancer. EUS is superior to CT for detecting the depth of invasion in the esophageal wall and mediastinal lymph node metastases, but CT is superior to EUS for detecting distant metastases. The ability of EUS to differentiate T2 from T3 tumors is particularly helpful for guiding treatment because patients with T2 tumors usually undergo primary surgical resection, whereas chemoradiation therapy is usually given to patients with T3 tumors. At institutions in which surgery is performed for both T2 and T3 tumors, however, this benefit of EUS is lost.

Figure 23-30 Normal contact between esophagus and descending thoracic aorta. There is direct contact between the esophagus and adjacent descending thoracic aorta.

The accuracy of EUS for nodal staging can be increased by transesophageal EUS-guided fine-needle aspiration (FNA) cytology of peritumoral lymph nodes in the mediastinum.¹⁷⁴ In one study, routine FNA of lymph nodes at EUS was found to have an accuracy of 93% for nodal staging versus an accuracy of 70% for EUS alone.¹⁷⁵ EUS with FNA can therefore improve local staging of esophageal cancer.

POSITRON EMISSION TOMOGRAPHY

PET using fluorine-18-deoxyglucose (FDG) is another useful test for staging esophageal cancer. Because these tumors and their metastases to the liver, lungs, cervical lymph nodes, and other sites are relatively FDG-avid (Figs. 23-37 and 23-38), PET or PET/CT can detect metastases that are not recognized on CT.¹⁷⁶ In one study, PET revealed metastases not visible on CT of the chest and upper abdomen in 17% of patients with esophageal cancer, including 38% of cervical lymph node metastases, 23% of bone metastases, and 15% of hepatic metastases.¹⁷⁷ PET is therefore particularly helpful when CT reveals no evidence of local invasion or distant metastases (Fig. 23-39). In another study, PET contributed important additional information for cancer staging in 14% of patients with esophageal cancer who underwent CT.¹⁷⁸

ULTRASONOGRAPHY OF THE NECK

Cervical lymph nodes appear to be of greater importance for esophageal cancer staging than has previously been recognized.

Figure 23-31 Aortic invasion by esophageal carcinoma. **A.** CT scan shows more than 90 degrees of contact between the esophageal tumor and aorta without intervening fat planes. This is a useful CT criterion for predicting aortic invasion. **B.** Line drawing also shows more than 90 degrees of contact between the tumor and aorta.

In one study, one third of patients who underwent esophagectomy for “curable” cancers of the thoracic esophagus were found to have cervical lymph node metastases when a lymph node dissection of the neck was performed at the time of esophagectomy.¹⁷⁹ Lymph node metastases were found to be as common in the neck as in the mediastinum. The frequency of cervical lymph node metastases directly correlates with the location of the tumor in the esophagus—80% of patients with tumors in the cervical esophagus have cervical lymph node metastases versus 52% with tumors in the proximal thoracic

Figure 23-32 Esophageal carcinoma without evidence of aortic invasion. **A.** CT scan shows less than 45 degrees of contact between the esophageal tumor and aorta. This finding indicates that the aorta is not invaded by tumor. **B.** Line drawing also shows less than 45 degrees of contact between the esophageal tumor and aorta.

Figure 23-33 Indeterminate CT scan for aortic invasion by esophageal cancer. **A.** CT scan shows between 45 and 90 degrees of contact between the esophageal tumor and aorta. This finding is indeterminate for aortic invasion. **B.** Line drawing also shows between 45 and 90 degrees of contact between the esophageal tumor and aorta.

Figure 23-34 Normal endoscopic ultrasound. This image shows all five layers (arrows) of the esophageal wall.

Figure 23-35 Endoscopic ultrasound of esophageal cancer. Endoscopic ultrasound shows a hypoechoic mass (M) causing focal widening of the esophageal wall. The thin black line peripherally (arrows) indicates that the tumor has not yet invaded the serosal fat.

Figure 23-36 Endoscopic ultrasound of lymph node metastasis from esophageal carcinoma. The enlarged node is manifested by a hypoechoic focus (arrow).

Figure 23-37 Liver metastasis from esophageal carcinoma on PET. This coronal PET image shows marked uptake of radionuclide in avid hepatic metastasis.

Figure 23-38 Cervical lymph node and pulmonary metastases from esophageal carcinoma on PET. This coronal PET image shows marked uptake of radionuclide (large white arrow) in a bulky esophageal tumor in the upper mediastinum. Also note uptake in metastases to a right cervical lymph node (yellow arrow) and right lung (small white arrow).

Figure 23-39 Value of PET for showing metastases not detected on CT scan. **A.** Barium study shows a circumferentially infiltrating carcinoma of the distal esophagus. **B.** Coronal PET image shows marked uptake of radionuclide in distal esophageal tumor (T). However, there is also uptake in metastases to the liver (*long arrow*), mediastinum (*medium arrow*), and a left cervical lymph node (*short arrow*). The PET scan has therefore dramatically altered the staging of this patient's disease. **C.** CT scan shows marked esophageal wall thickening by tumor (*arrow*). However, this lesion is potentially resectable without CT scan findings of local or distant metastases. (Note how there is less than 45 degrees of contact between the tumor and adjacent aorta.)

esophagus, 29% with tumors in the midthoracic esophagus, and 9% with tumors in the distal thoracic esophagus.¹⁸⁰

Because of the high frequency of cervical lymph node metastases from esophageal cancer, Asian and European authors have advocated ultrasonography of the neck with FNA for suspicious lymph nodes as another imaging test for staging esophageal cancer.^{181,182} Neck ultrasonography is performed with a high-frequency transducer in the range of 7.5 to 10 MHz. This examination is relatively easy to perform because the lymph nodes of interest in the neck are within 3 cm of the skin surface. Lymph nodes are considered to be abnormal if they have a diameter larger than 5 mm or a short-to-long ratio more than 50%.¹⁸³ In one study, ultrasonography of the neck with FNA of suspicious nodes had a sensitivity of 88%, specificity of 59%, and accuracy of 78% for detecting cervical lymph node metastases from esophageal cancer.¹⁸⁴

STAGING ALGORITHM

CT is usually recommended as the initial test for staging esophageal cancer. If CT reveals local invasion or distant metastases, no further imaging is warranted. If, however, CT is negative or indeterminate for local invasion or distant metastases, the patient can be referred for EUS. If the tumor still appears to be resectable on EUS, then PET or PET/CT can be performed to detect local invasion or distant metastases not recognized on CT or EUS. Further investigation is needed to determine whether ultrasonography or CT of the neck should be performed routinely to assess for cervical lymph node metastases in these patients.

Treatment

Depending on the stage of the tumor at the time of diagnosis, esophageal cancer may be treated by curative or palliative measures. Curative therapy includes surgery, radiation, and surgery combined with preoperative or postoperative radiation or chemotherapy. Palliative therapy includes surgery, radiation, chemotherapy, placement of an indwelling esophageal prosthesis, and laser treatment.

SURGERY

Curative resection of a carcinoma in the distal two thirds of the esophagus usually requires an esophagogastrectomy and gastric pull-through. Resection of a more proximal lesion may require a free jejunal graft for reconstruction of the pharyngoesophagus. Palliative surgery in patients with advanced esophageal cancer usually consists of an esophageal bypass procedure to control symptoms of obstruction or fistula formation. The most common bypass procedures include colonic interposition and creation of a gastric tube. Palliation may also be achieved by passage of an esophageal prosthesis (usually an expandable metallic stent) to bypass an obstruction or fistula. The normal and abnormal appearances after surgery or other palliative procedures for esophageal cancer are discussed in Chapter 27.

RADIATION THERAPY

Radiation therapy may be used for palliative or definitive treatment of esophageal cancer. Squamous cell carcinomas tend to

be more radiosensitive than adenocarcinomas.¹⁸⁵ Tumors in the cervical or upper thoracic esophagus also tend to be more radiosensitive than those in the middle or distal thoracic esophagus.¹⁸⁵ Partial or total regression of tumor occurs in most patients who undergo this form of treatment.¹⁸⁶⁻¹⁸⁸ Although they may have substantial amelioration of dysphagia in the initial months after therapy, tumor subsequently recurs locally in 30% to 85% of cases.^{185,188-190} Even when the cancer is eradicated from the esophagus, these patients often die as a result of widespread metastases to the liver, lungs, or mediastinum.^{185,188,191} Increased morbidity or mortality may also be attributed to complications of radiation therapy, such as esophageal ulceration, perforation, and fistula formation.^{190,192} As a result, the prognosis after radiation therapy is comparable to or slightly worse than that after surgery, with an average survival of only 9 to 10 months.

Partial regression of tumor after radiation therapy may be recognized on serial barium studies by a decrease in the size and bulk of the lesion. With total regression of tumor, esophagography may reveal a normal esophagus or a benign-appearing stricture at the site of the original lesion (Fig. 23-40).^{188,189,193,194} In most cases, these strictures appear as smooth, tapered areas of narrowing without evidence of nodularity, mass effect, or ulceration to suggest residual tumor. Even when there is total regression of tumor, however, these patients often die as a result of distant metastases, presumably because of unrecognized lymphatic involvement at the time of therapy.¹⁸⁸ Thus, disappearance of the cancer on radiologic or endoscopic studies does not necessarily indicate a cure.

Although most patients have an initial clinical response to radiation therapy, recurrent dysphagia often occurs within 3 to 9 months after treatment because of local recurrence of tumor.^{185,188,189} Recurrent carcinoma may be recognized on barium studies by the development of a polypoid, ulcerative, or infiltrating lesion within or just beyond the margins of the original radiation portal.¹⁸⁸ However, an exacerbation of symptoms in these patients may be caused not only by recurrent tumor but also by benign radiation strictures, fistula formation, perforation, or opportunistic esophageal infections such as *Candida* and herpes esophagitis.¹⁸⁸ Thus, radiologic studies may differentiate recurrent carcinoma from other complications in these patients.

CHEMORADIATION THERAPY

Initial reports suggested that combined radiation and chemotherapy of patients with esophageal carcinoma produced an immediate and dramatic response, but that the long-term benefits of this approach were questionable. Preoperative chemoradiation therapy has also been advocated as an adjunct to surgery for patients with locally advanced tumors or regional lymphadenopathy.² Unfortunately, conflicting data have been reported about the value of multimodality therapy. In a study of patients with esophageal adenocarcinoma, preoperative chemoradiation therapy was found to be superior to surgery alone, with median survivals of 15 and 11 months, respectively.¹⁹⁵ In another study of patients with squamous cell carcinoma of the esophagus, however, preoperative chemoradiation therapy did not improve overall survival.¹⁹⁶ Nevertheless, chemoradiation therapy is a viable alternative to surgery in patients with advanced disease or medical conditions that preclude surgery.

Figure 23-40 Total regression of esophageal carcinoma with a benign-appearing residual stricture after radiation therapy.

A. Initial esophagogram shows an advanced, infiltrating carcinoma in the midesophagus. **B.** Second study 4 months after radiation therapy shows partial regression of the tumor, with residual areas of shallow ulceration. **C.** Third study 2 months later shows further regression of the lesion, with a smooth, tapered, benign-appearing radiation stricture in this location. Metastases

Esophageal metastases are found at autopsy in less than 5% of patients dying of carcinoma. Most cases result from direct invasion by primary malignant tumors of the stomach, lung, and neck or from contiguous involvement by tumor-containing lymph nodes in the mediastinum. These various forms of esophageal involvement by metastatic tumor produce characteristic radiographic findings that are discussed separately in later sections.

SITES OF ORIGIN

Carcinoma of the stomach accounts for about 50% of all esophageal metastases.¹ Tumors involving the gastric cardia or fundus may invade the distal esophagus by contiguous spread through the diaphragmatic hiatus. Carcinomas of the lung and breast are other less common causes of esophageal metastases.²⁻⁴ Most cases result from direct extension of tumor to the esophagus or from contiguous esophageal involvement by lymphadenopathy in the posterior mediastinum. The esophagus may also be involved by contiguous spread of malignant tumors in the neck, such as laryngeal, pharyngeal, and thyroid carcinomas. Rarely, the esophagus may be involved by hematogenous metastases from tumors arising in distant locations such as the kidney, liver, rectum, prostate, cervix, and skin.⁵⁻⁹ Thus, most malignant tumors are capable of metastasizing to the esophagus.

CLINICAL FINDINGS

Patients with esophageal metastases may present with dysphagia as a result of esophageal compression by enlarged mediastinal lymph nodes or actual invasion of the esophagus by tumor. Although the presence of esophageal metastases usually indicates a poor prognosis, some patients (particularly those with breast or lung cancer) may present with dysphagia as the initial manifestation of their disease.^{2,10} Also, patients with breast cancer often have late-onset metastases to the esophagus, with an average interval of approximately 8 years from the time of diagnosis to the development of dysphagia.^{4,11} When dysphagia occurs, these patients usually have widespread metastatic disease.^{3,11}

RADIOGRAPHIC FINDINGS

Direct Invasion

Direct invasion of the cervical or thoracic esophagus by carcinoma of the larynx, pharynx, thyroid, or lung produces characteristic findings on barium studies. Early invasion may be manifested by a smooth or slightly irregular indentation on the esophagus with gently sloping, obtuse borders and a contiguous soft tissue mass in the adjacent mediastinum or neck. The area of involvement may have a more serrated, scalloped, or nodular appearance as the esophageal wall is further infiltrated by tumor (Fig. 24-1). Eventually, there may be circumferential narrowing of the esophagus with mass effect, nodularity, ulceration, or obstruction (Fig. 24-2). Rarely, thyroid cancer invading the esophagus may be manifested by an expansile intraluminal mass, mimicking the appearance of a spindle cell carcinoma (see later, "Spindle Cell Carcinoma").¹²

Figure 24-1 Direct esophageal invasion by carcinoma of the lung. There is eccentric mass effect and narrowing of the esophagus by tumor in the adjacent mediastinum. The scalloped contour of the esophagus in this region indicates direct invasion by tumor. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 24-2 Direct esophageal invasion by carcinoma of the lung. This patient has a long segment of irregular narrowing in the midesophagus caused by circumferential involvement by metastatic tumor in the mediastinum. (Courtesy Robert A. Goren, MD, Philadelphia.)

Secondary esophageal involvement by carcinoma of the gastric cardia or fundus may be manifested radiographically by a polypoid mass extending from the fundus into the distal esophagus (Fig. 24-3) or by irregular narrowing of the distal esophagus without a discrete mass.^{13,14} Esophageal involvement is usually confined to a short segment of the distal esophagus but may extend as far proximally as the aortic arch.¹³ Occasionally, these tumors may cause smooth, tapered narrowing of the distal esophagus at or near the gastroesophageal junction, mimicking the appearance of achalasia (see later, “[Secondary Achalasia](#)”).

When the distal esophagus appears to be involved by tumor on barium studies, the gastric cardia and fundus should also be evaluated radiographically to determine whether there is associated gastric involvement. In some cases, barium studies may demonstrate an obvious malignant tumor in the stomach (see Fig. 24-3). In others, however, the presence of tumor in the gastric fundus may be recognized only by distortion or obliteration of the normal anatomic landmarks at the cardia associated with relatively subtle areas of nodularity, mass effect, or ulceration (Fig. 24-4).^{14,15} Thus, a meticulous double-contrast examination of the fundus is essential to rule out an underlying carcinoma of the cardia in these patients.

Contiguous Involvement by Mediastinal Lymph Nodes

Although any neoplasm that metastasizes to mediastinal lymph nodes may secondarily involve the esophagus, breast and lung cancer are the most common underlying malignant tumors in these patients.¹¹ Because of the proximity of the midesophagus to subcarinal lymph nodes, esophageal involvement by mediastinal lymphadenopathy usually occurs at this level.^{10,16} Barium studies typically reveal a smooth or slightly lobulated extrinsic indentation on the esophagus at or just below the carina (Fig. 24-5A).^{10,16} When tumor directly invades the esophagus, it may have a more irregular contour, often with areas of ulceration (Fig. 24-6).^{1,4,6} Eventually, the esophageal wall may be circumferentially infiltrated by tumor, producing an area of concentric narrowing with a surrounding soft tissue mass (Fig. 24-7).^{2,4,6} When esophageal involvement by mediastinal tumor is suspected on barium studies, CT should be performed to show the location and extent of lymphadenopathy in the mediastinum (Fig. 24-5B).

Hematogenous Metastases

True blood-borne or hematogenous metastases to the esophagus are extremely uncommon. Most cases are caused by

Figure 24-3 Direct esophageal invasion by gastric carcinoma. **A.** Double-contrast esophagogram shows a polypoid lesion in the distal esophagus that extends inferiorly to the gastroesophageal junction. **B.** Lateral view of the gastric fundus shows a large fundal mass (black arrows) containing an eccentric area of ulceration (white arrow). This patient had a primary gastric carcinoma invading the distal esophagus. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

carcinoma of the breast, but other distant tumors may also metastasize hematogenously to the esophagus. Surprisingly, however, malignant melanoma (which has the highest percentage of blood-borne metastases to the gastrointestinal tract) rarely involves the esophagus.^{5,9} Whatever the origin, blood-borne metastases to the esophagus usually appear on barium studies as short, eccentric strictures (usually in the middle third of the esophagus) with intact overlying mucosa and smooth, tapered margins (Fig. 24-8).^{1,4,6,17} Although blood-borne metastases to the esophagus tend to be infiltrating lesions, they occasionally may be manifested by one or more discrete submucosal masses or centrally ulcerated bull's-eye lesions.¹⁷

DIFFERENTIAL DIAGNOSIS

A smooth or slightly lobulated indentation on the esophagus may be caused by a variety of extrinsic mass lesions such as benign tumors and cysts in the mediastinum, aberrant vessels, and an ectatic aorta or aortic aneurysm compressing the esophagus. In contrast, esophageal invasion by metastatic tumor should be suspected when the area of mass effect has an irregular, serrated, or nodular contour or is associated with ulceration. As a result, malignant invasion of the esophagus usually can be

distinguished from benign lesions in the mediastinum that are compressing but not invading the esophagus.

The differential diagnosis for upper or midesophageal strictures caused by metastatic tumor includes Barrett's esophagus and scarring from mediastinal irradiation, caustic ingestion, eosinophilic esophagitis, or oral medications such as potassium chloride and quinidine. When these patients are known to have a previously irradiated malignant tumor in the thorax, the major diagnostic considerations include a benign radiation stricture and recurrent tumor. In such cases, computed tomography (CT) may be used to differentiate recurrent tumor from a radiation stricture by showing a mediastinal mass or lymphadenopathy in the region of the stricture.

Secondary Achalasia

The terms *secondary achalasia* and *pseudoachalasia* are used interchangeably to describe an entity in which the clinical, radiographic, endoscopic, and manometric features may be indistinguishable from those of primary, or idiopathic, achalasia. Malignancy-induced secondary achalasia is an uncommon condition, accounting for only 2% to 4% of patients with findings of achalasia at manometry.¹⁸ Almost 75% of

cases are caused by carcinoma of the gastric cardia or fundus directly invading the gastroesophageal junction or distal esophagus.^{19,20} Less frequently, hematogenous metastases from other malignant tumors such as breast, lung, pancreatic, uterine, and prostate cancer or even lymphoma involving the gastroesophageal junction may produce identical findings.^{8,19,21-23} Other benign causes of secondary achalasia include Chagas' disease, amyloidosis, and Nissen fundoplication.²⁴⁻²⁶ It is important to differentiate primary and secondary achalasia because primary achalasia may be treated by pneumatic dilation, botulinum toxin injection, or laparoscopic myotomy, whereas secondary achalasia often necessitates chemotherapy or other treatment for widespread metastatic disease.

PATHOGENESIS

Primary and secondary achalasia are characterized by absent esophageal peristalsis and a hypertensive lower esophageal sphincter that fails to relax normally in response to deglutition. In patients with primary achalasia, the motor disorder is thought to be caused by degeneration and loss of the ganglion cells of Auerbach's plexus in the esophagus. However, the precise mechanism whereby metastases produce this motility disorder is uncertain. Some patients have tumor directly invading the distal esophagus with actual destruction of myenteric ganglia.²⁷ However, others have tumor confined to the

Figure 24-4 Direct esophageal invasion by carcinoma of the gastric cardia. Double-contrast view of the fundus shows obliteration of the normal anatomic landmarks at the cardia with a centrally ulcerated polypoid lesion (straight arrows) extending into the distal esophagus (curved arrow). (From Levine MS, Laufer I, Thompson JJ: Carcinoma of the gastric cardia in young people. *AJR* 140:69-72, 1983.)

Figure 24-5 Esophageal compression by mediastinal lymphadenopathy from carcinoma of the lung. **A.** Barium study shows a large extrinsic indentation (arrows) on the anterolateral wall of the midesophagus just below the carina. **B.** CT scan shows bulky mediastinal and subcarinal adenopathy as the cause of this finding. An endobronchial lesion (arrow) is also seen in the left main bronchus near the carina. This patient was found to have a small cell carcinoma of the lung. (Courtesy Vincent Low, MD, Perth, Australia.)

Figure 24-6 Esophageal involvement by mediastinal lymphadenopathy from carcinoma of the cervix. There is eccentric mass effect on the midesophagus with an irregular contour and areas of ulceration caused by esophageal invasion by tumor in adjacent subcarinal nodes. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 24-7 Circumferential esophageal involvement by metastatic breast cancer in the mediastinum. A relatively smooth, tapered area of narrowing is seen in the midesophagus. However, a surrounding soft tissue mass (arrows) in the mediastinum suggests esophageal encasement by lymphadenopathy. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

gastroesophageal junction without involvement of the neural plexus in the esophagus.²⁸ In such cases, the motor disorder may be caused by extraesophageal metastases to the vagus nerve or dorsal motor nucleus of the vagus nerve in the brain stem.^{20,28} Secondary achalasia may also occur as a paraneoplastic phenomenon caused by circulating tumor products that alter esophageal motor function.⁸ Finally, malignant neuroendocrine tumors (particularly small cell carcinoma of the lung) may express a variety of neural antigens that initiate an autoimmune response with circulating antibodies—known as anti-Hu antibodies—that cause neural degeneration and secondary achalasia.^{29,30}

CLINICAL FINDINGS

Although dysphagia occurs in primary and secondary achalasia, various clinical features are helpful for distinguishing these entities. Most patients with primary achalasia are between 20 and 50 years of age, and they have dysphagia for a mean duration of 4 to 6 years before seeking medical attention.^{18,31} In contrast, most patients with secondary achalasia are more than 60 years of age, and the duration of symptoms is usually less than 6 months.^{18,31} Secondary achalasia also is far more likely to

be associated with weight loss.³² An underlying malignant tumor should therefore be suspected whenever achalasia is diagnosed in older patients with recent onset of dysphagia and weight loss.^{18,31,32} Nevertheless, some patients with primary achalasia may be older than 60 years and others may have a relatively short duration of symptoms.^{31,33,34} Thus, it is not always possible to differentiate these conditions on clinical grounds.

RADIOGRAPHIC FINDINGS

Secondary achalasia is classically manifested on barium studies by absent esophageal peristalsis and smooth, tapered narrowing of the distal esophagus, producing a bird-beak configuration at or abutting the gastroesophageal junction (Fig. 24-9).^{8,19,31,35} Although the radiographic appearance may closely resemble that of primary achalasia, infiltration of the distal esophagus by tumor in secondary achalasia sometimes causes asymmetric or eccentric narrowing, abrupt transitions, rigidity, and mucosal nodularity or ulceration.^{31,35} Another important sign of malignancy is the length of the narrowed segment, which may extend 3.5 cm or more above the gastroesophageal junction in secondary achalasia (Fig. 24-10) but rarely extends this

far proximally in patients with primary achalasia.³¹ Finally, the degree of esophageal dilation is usually less in patients with secondary achalasia because of the rapid onset of disease.³¹ When findings of achalasia are present on barium studies, a narrowed distal esophageal segment longer than 3.5 cm with little or no proximal dilation in an older patient with recent onset of dysphagia should therefore be highly suggestive of secondary achalasia, even in the absence of other suspicious radiographic findings.³¹

Because secondary achalasia is usually caused by carcinoma of the gastric cardia or fundus invading the distal esophagus, careful radiologic evaluation of the fundus is essential in these patients. Not infrequently, an obvious polypoid, ulcerated, or infiltrating carcinoma may be demonstrated in the fundus (see Fig. 24-9B). With less advanced lesions, no gross abnormalities may be demonstrated in the gastric fundus on conventional single-contrast barium studies. However, double-contrast studies may reveal subtle evidence of tumor distorting or obliterating the normal anatomic landmarks at the gastric cardia (see Fig. 24-10).^{14,15} In contrast, the characteristic rosette that demarcates the gastric cardia on double-contrast studies should be normal in patients with primary achalasia.

CT is often helpful for differentiating primary and secondary achalasia. Patients with primary achalasia typically have little or no gastric esophageal wall thickening (Fig. 24-11A) and no evidence of mediastinal lymphadenopathy or a mass at the cardia on CT (Fig. 24-11B).^{36,37} In some cases, however, CT may reveal a pseudomass at the cardia because of inadequate distention of this region.³⁸ In contrast, patients with secondary achalasia often have a thickened wall in the distal esophagus on CT, and the thickened wall tends to be lobulated and asymmetric (Fig. 24-12A). CT may also reveal a soft tissue mass at the cardia (Fig. 24-12B), mediastinal lymphadenopathy, and the presence of pulmonary, pleural, or hepatic metastases.^{39,40} CT is also helpful for detecting the site of the primary tumor in patients with secondary achalasia caused by carcinoma of the gastric cardia or fundus, lung, or pancreas or other malignant neoplasms in the chest or abdomen.

Figure 24-8 Hematogenous metastasis to the esophagus from carcinoma of the breast. The lesion is manifested by a short, benign-appearing stricture (arrow) in the midesophagus. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 24-9 Secondary achalasia caused by gastric carcinoma. **A.** There is smooth, tapered narrowing of the distal esophagus, producing the characteristic bird-beak appearance of primary achalasia. **B.** However, a view of the stomach reveals a diffusely infiltrating carcinoma of the gastric body and fundus that has invaded the distal esophagus.

Figure 24-10 Secondary achalasia caused by carcinoma of the gastric cardia. There is smooth, tapered narrowing of the distal esophagus, but the narrowed segment extends a considerable distance from the gastroesophageal junction (a finding not often seen in patients with primary achalasia). Also note how the tumor causes marked nodularity of the gastric fundus with obliteration of the normal anatomic landmarks at the cardia. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Lymphoma

The esophagus is the least common site of gastrointestinal involvement by lymphoma, accounting for only about 1% of cases.⁴¹ Both non-Hodgkin's and, less commonly, Hodgkin's lymphoma may involve the esophagus. These patients almost always have generalized lymphoma with direct invasion of the esophagus by lymphomatous nodes in the mediastinum, contiguous spread of lymphoma from the gastric fundus, or synchronous development of lymphoma in the esophagus.⁴²⁻⁴⁵ Rarely, primary esophageal lymphoma (usually Hodgkin's lymphoma) may occur without extraesophageal disease.⁴⁶⁻⁵¹ Cases of AIDS-related primary esophageal lymphoma have also been reported.^{52,53} When esophageal lymphoma is suspected, endoscopy should be performed with deep esophageal biopsy specimens to confirm the diagnosis. However, false-negative biopsy specimens have been reported in 25% to 35% of cases because of the patchy nature of the disease and sampling error.⁵¹ Thus, some patients may require surgery for a definitive diagnosis.

CLINICAL FINDINGS

Most patients with esophageal lymphoma have no esophageal symptoms, so the diagnosis is usually made at autopsy in patients with widespread disease.^{41,42} However, some patients may develop dysphagia as a result of esophageal narrowing or obstruction by tumor.^{42,43} Rarely, they may present with dysphagia as the initial manifestation of their disease.⁵⁴

RADIOGRAPHIC FINDINGS

Secondary involvement of the esophagus by gastric lymphoma may be manifested on barium studies by irregular narrowing of the distal esophagus caused by contiguous

Figure 24-11 Primary achalasia on CT. A. CT scan shows a dilated esophagus (arrowheads) without esophageal wall thickening or mediastinal adenopathy. **B.** Another scan more caudally shows no evidence of a soft tissue mass at the gastroesophageal junction. (Note barium in the gastric fundus.) This patient had long-standing primary achalasia.

Figure 24-12 Secondary achalasia on CT. A. CT scan shows asymmetric thickening of the esophageal wall (arrowhead) in the distal esophagus at the level of beaklike narrowing seen on a prior barium study (not shown). **B.** Another CT image more caudally shows an asymmetric soft tissue mass (arrowheads) at the gastroesophageal junction protruding into the medial aspect of the gas-filled fundus. This patient had a carcinoma of the cardia causing secondary achalasia.

spread of tumor from the gastric fundus (Fig. 24-13).^{42-44,55} In such cases, careful radiologic examination of the gastric cardia and fundus may demonstrate a polypoid, ulcerated, or infiltrating lesion in the fundus secondary to the underlying gastric lymphoma. Transcardiac extension of gastric lymphoma is thought to occur in about 10% of patients.⁵⁵ However, these lesions cannot be distinguished radiographically from carcinoma of the gastric fundus invading the distal esophagus.

Mediastinal lymphoma may cause extrinsic compression of the esophagus, resulting in a smooth indentation with obtuse, gently sloping borders.⁴² Further esophageal involvement may be manifested by a more irregular or serrated contour abnormality secondary to invasion of the wall by tumor. Eventually, mediastinal lymphoma may cause diffuse esophageal narrowing (Fig. 24-14A). CT is particularly useful for determining the extent of disease in the mediastinum (Fig. 24-14B). Other patients may develop esophageal-airway fistulas, usually as a complication of radiation therapy.^{56,57}

Intrinsic esophageal lymphoma may be manifested by a spectrum of abnormalities, including submucosal nodules, enlarged folds, polypoid masses, and strictures. The most common finding is a polypoid or ulcerated mass or an infiltrating lesion indistinguishable from esophageal carcinoma (Fig. 24-15).^{42-44,48-52} Less frequently, lymphomatous infiltration of the submucosa may result in enlarged, tortuous longitudinal folds, mimicking the appearance of varices.⁴²⁻⁴⁵ Occasionally, discrete submucosal masses may be found in the esophagus, suggesting multiple leiomyomas.^{43,44} Other patients may have innumerable small submucosal nodules in the esophagus (Fig. 24-16).^{58,59} Although leukemic infiltrates, hematogenous metastases, and Kaposi's sarcoma have also been described as unusual causes of submucosal nodules, the lesions tend to be larger and less numerous in these patients. Rarely, esophageal lymphoma may cause aneurysmal dilation similar to that found in the small intestine.⁵¹

Figure 24-13 Esophageal involvement by gastric lymphoma. There is irregular narrowing (arrows) of the distal esophagus caused by contiguous spread of lymphoma from the gastric fundus. Carcinoma of the gastric cardia invading the distal esophagus could produce identical findings. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 24-14 Esophageal involvement by mediastinal lymphoma. **A.** Barium study shows a long segment of smooth narrowing in the lower third of the esophagus secondary to circumferential encasement by mediastinal lymphadenopathy in a patient with lymphoma. **B.** CT scan in another patient with large cell lymphoma of the mediastinum shows extensive mediastinal adenopathy compressing the esophagus (arrowhead) and superior vena cava (arrow). (**A** courtesy Kyunghie C. Cho, MD, Newark, NJ; **B** courtesy Richard M. Gore, MD, Evanston, IL.)

Spindle Cell Carcinoma

Malignant polypoid epithelial tumors of the esophagus containing both carcinomatous and sarcomatous elements are exceedingly uncommon, accounting for only 0.5% to 1.5% of all esophageal neoplasms.⁶⁰ Terms formerly used to describe these lesions include *carcinosarcoma*, *pseudosarcoma*, *polypoid carcinoma*, and *spindle cell variant of squamous cell carcinoma*. However, many investigators believe that these lesions represent various expressions of a single malignant tumor, which has been designated *spindle cell squamous carcinoma* or, simply, *spindle cell carcinoma*.⁶¹⁻⁶³

PATHOLOGY

In the past, carcinosarcomas of the esophagus were thought to contain a mixture of carcinomatous and sarcomatous elements.^{64,65} In contrast, pseudosarcomas were thought to be composed primarily of sarcoma-like spindle cells with adjacent areas of squamous cell carcinoma.⁶⁶⁻⁶⁸ Because the sarcomatous portion of the tumor rarely metastasized to other structures, pseudosarcomas were thought to be less aggressive lesions that had a better prognosis than carcinosarcomas.⁶⁵ In subsequent studies, however, it was shown that metastases also occurred

from the sarcomatous portion of so-called pseudosarcomas and that these lesions behaved as aggressively as carcinosarcomas.^{61,69} Thus, carcinosarcoma and pseudosarcoma appear to be the same pathologic entity, with varying degrees of anaplastic spindle cell metaplasia of the carcinomatous portion of the tumor.^{61,63,70}

CLINICAL FINDINGS

Patients with spindle cell carcinoma almost always present with dysphagia and weight loss.⁷¹ Most patients are older men who often have a history of cigarette smoking or alcohol consumption.^{68,71} The clinical presentation is therefore indistinguishable from that of squamous cell carcinoma.

It has been suggested that spindle cell carcinoma has a better prognosis than squamous cell carcinoma because these tumors tend to remain superficial, with local invasion and regional or distant metastases occurring late in the course of the disease.^{64,72} However, other investigators have found that as many as 50% of patients with spindle cell carcinoma have metastatic disease at the time of diagnosis, and the overall 5-year survival rate is only 2% to 8%.^{65,71} Thus, the prognosis of this tumor is probably comparable to that of squamous cell carcinoma.

Figure 24-15 Primary AIDS-related non-Hodgkin's lymphoma of the esophagus. There is an irregular, ulcerated area of narrowing with a shelflike proximal border in the distal thoracic esophagus. This lesion is indistinguishable from an advanced esophageal carcinoma. (Courtesy Jackie Brown, MD, Vancouver, Canada.)

RADIOGRAPHIC FINDINGS

Spindle cell carcinomas tend to be located in the mid or lower esophagus, appearing on barium studies as large polypoid masses that expand or dilate the lumen without causing obstruction (Fig. 24-17).^{62,63,65,69,72} Similarly, CT may reveal a bulky mass expanding the lumen of the esophagus. In some cases, barium may form a dome over the intraluminal portion of the tumor, producing a cupola effect.^{62,63,65} Occasionally, a broad-based or narrow pedicle may be observed.^{62,63,68,69} Rarely, torsion of the pedicle results in spontaneous sloughing of the tumor.⁶⁸ Spindle cell carcinomas usually can be differentiated from squamous cell carcinomas and adenocarcinomas because the latter tumors tend to infiltrate and narrow the lumen, producing very different radiographic findings.⁷³ Rarely, however, spindle cell carcinomas may be infiltrating lesions indistinguishable from squamous cell carcinomas or adenocarcinomas.^{65,71}

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for an expansile polypoid intraluminal mass includes other benign and malignant tumors of the esophagus. Benign lesions such as a giant fibrovascular polyp or leiomyoma may occasionally produce similar findings, but these

lesions tend to have a smoother contour and are less lobulated.⁷⁴ Primary malignant melanoma of the esophagus is another rare neoplasm characterized by an expansile intraluminal mass indistinguishable from spindle cell carcinoma (see later, “**Malignant Melanoma**”). Other unusual malignant tumors of the esophagus, such as lymphoma, leiomyosarcoma, and Kaposi's sarcoma, might also be considered. A definitive diagnosis of spindle cell carcinoma can therefore be made only on histologic grounds.

Leiomyosarcoma

Leiomyosarcomas of the esophagus are rare, low-grade, malignant tumors characterized by slow growth and late metastases.^{75,76} These tumors are almost always thought to arise de novo rather than from preexisting leiomyomas.^{77,78} They are usually located in the distal two thirds of the esophagus because this is the portion of the esophagus that is lined by smooth muscle.^{79,80} The lesions may eventually spread by direct extension to the pleura, pericardium, diaphragms, and stomach, or they may metastasize hematogenously to the liver, lungs, and bones.^{76,78,79} Because of their relatively slow growth rates, esophageal leiomyosarcomas have a better prognosis than squamous cell carcinomas, with 5-year survival rates approaching 35%.^{79,81} Nevertheless, rapid progression of esophageal leiomyosarcomas has occasionally been documented.⁸¹ Leiomyosarcomas involving the esophagus should be differentiated from gastrointestinal stromal tumors (GISTs), which also have malignant potential (see Chapter 22).

CLINICAL FINDINGS

Esophageal leiomyosarcomas are usually found in middle-aged or older patients^{76,82} and are slightly more common in men than in women.^{79,82} Dysphagia is the most common presenting clinical complaint, but dysphagia can be minimal or absent if the tumor has a predominantly exophytic pattern of growth with little encroachment on the lumen.⁸³ When dysphagia does occur, it is often present for a longer interval (6-12 months) than in patients with esophageal carcinoma because of slower growth of these tumors.⁷⁹ Although rare, gastrointestinal bleeding may occur if the lesion is ulcerated.⁷⁷

An esophagectomy or esophagogastrectomy is the treatment of choice for esophageal leiomyosarcomas.^{76,79,80,82} Even when metastases are present, resection of the primary tumor may lead to prolonged survival of these patients. Because leiomyosarcomas are radiosensitive, bulky lesions can be palliated by radiation therapy in nonsurgical candidates.^{76,79,80}

RADIOGRAPHIC FINDINGS

Esophageal leiomyosarcomas sometimes contain large exophytic components that can be recognized on chest radiographs by the presence of a mediastinal mass.^{76,83,84} Rarely, chest radiographs reveal dense calcification within the tumor.⁸⁵ Leiomyosarcomas typically appear on barium studies as large, lobulated intramural masses containing areas of ulceration or tracking (Fig. 24-18A).⁸³ These tumors therefore have the same radiographic features as malignant GISTs in the stomach and small bowel. Less commonly, they appear as polypoid, expansile intraluminal masses or as infiltrative lesions with irregular luminal narrowing.^{75,78,83,84,86}

Figure 24-16 Generalized non-Hodgkin's lymphoma involving the esophagus. Double-contrast images of the middle (**A**) and distal (**B**) thoracic esophagus show innumerable 3- to 10-mm submucosal nodules extending from the thoracic inlet to the gastroesophageal junction. This appearance could initially be mistaken for varices, but the diffuse distribution and discrete margins of the lesions allow them to be differentiated from varices. **C.** Endoscopic photograph reveals multiple, discrete submucosal nodules that had a whitish-yellow appearance on visual examination. **D.** Repeat esophagogram obtained 2 months after chemotherapy shows almost complete healing of the submucosal nodules seen on the earlier study. (From Levine MS, Sunshine AG, Reynolds JC, et al: Diffuse nodularity in esophageal lymphoma. *AJR* 145:1218-1220, 1985.)

Figure 24-17 Spindle cell carcinoma of the esophagus. There is a large polypoid intraluminal mass in the midesophagus that expands the lumen without causing obstruction. This appearance is typical of spindle cell carcinoma but can also be seen with primary malignant melanoma of the esophagus (see Fig. 24-19). (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Esophageal leiomyosarcomas are characterized on CT by heterogeneous masses containing large exophytic components, central areas of low density, and extraluminal gas or contrast material within the tumor secondary to necrosis and cavitation (Fig. 24-18B).^{78,80,81,83} Similar CT findings have been reported for malignant GISTs involving the stomach and small bowel.

Esophageal leiomyosarcomas may be manifested on magnetic resonance imaging (MRI) scans by esophageal masses that are isointense with skeletal muscle on T1-weighted images (Fig. 24-18C) and hyperintense on T2-weighted images (Fig. 24-18D).^{83,87} MRI may also reveal a central signal void caused by extraluminal gas within the tumor (see Figs. 24-18C and D).⁸³

Esophageal leiomyosarcomas are characterized on endoscopic sonography by well-defined hyperechoic masses arising from the muscular layer of the esophageal wall.⁸¹ These tumors can also be recognized on angiography as hypervascular masses with tumor vessels, dilated vascular channels or venous lakes, and early venous drainage.⁷⁸

DIFFERENTIAL DIAGNOSIS

Esophageal leiomyosarcomas that appear on barium studies as intramural masses must be differentiated from leiomyomas and other benign mesenchymal tumors in the esophagus. However, these benign intramural lesions tend to be smaller and less lobulated and rarely contain areas of ulceration or tracking. Leiomyosarcomas that appear as polypoid masses must be differentiated from spindle cell sarcoma, malignant melanoma, lymphoma, Kaposi's sarcoma, and a giant fibrovascular polyp, but the latter neoplasm usually has a much smoother contour and almost always arises in the cervical esophagus near the cricopharynx.⁷⁴ Finally, leiomyosarcomas that appear as infiltrative lesions must be differentiated from a squamous cell carcinoma or adenocarcinoma arising in Barrett's mucosa.⁷³

Malignant Melanoma

Primary malignant melanoma of the esophagus is a rare but aggressive tumor that accounts for less than 1% of all malignant esophageal neoplasms.⁸⁸ In the past, these lesions were thought to represent metastases from occult melanomas of the eye, skin, or anus. However, esophageal metastases are rarely found in patients with documented melanomas elsewhere.^{5,9} The seeming paradox of developing melanoma in a structure such as the esophagus is explained by the fact that small numbers of melanocytes are present in the esophageal mucosa in 2% to 8% of patients.⁸⁹⁻⁹¹ As in the skin, esophageal melanoma presumably develops because of malignant degeneration of these preexisting melanocytes. A review of the literature suggests that primary malignant melanoma is at least 10 times more common than metastatic melanoma involving the esophagus.⁸⁸

CLINICAL FINDINGS

Primary esophageal melanoma is an extremely aggressive tumor that is usually diagnosed in older adults. Most patients present with dysphagia and weight loss,⁸⁸ but the diagnosis is rarely suggested on clinical grounds. These tumors can sometimes be recognized at endoscopy as darkly pigmented masses, but pigmentation is not always apparent on visual inspection.⁸⁸ The treatment of primary esophageal melanoma is surgical; an extensive esophageal resection is usually performed. However, these tumors tend to be advanced lesions at the time of diagnosis. As a result, affected individuals have a dismal prognosis, with 5-year survival rates of less than 5% and an average overall survival of only 10 to 13 months from the time of diagnosis.^{88,92}

RADIOGRAPHIC FINDINGS

Esophageal melanomas have strikingly similar findings on barium studies, appearing as bulky, polypoid intraluminal masses that expand the esophagus without causing obstruction (Fig. 24-19).⁹³⁻⁹⁶ CT may also reveal a large soft tissue mass expanding the esophagus.^{95,96} These findings occur because melanoma tends to grow intraluminally along the long axis of the esophagus, producing a polypoid mass that widens the lumen as it enlarges.⁹⁵ Most esophageal melanomas are located in the lower half of the esophagus,⁸⁸ probably because of the greater concentration of melanocytes in this region.⁸⁹⁻⁹¹

Figure 24-18 Esophageal leiomyosarcoma. **A.** Barium study shows a giant intramural mass (*large arrows*) with a bulky exophytic component in the mediastinum (*open arrows*). Note the relatively small central ulcer (*small arrow*) within the lesion. **B.** CT scan shows a heterogeneous mass (*white arrows*) in the left side of the mediastinum with central areas of low density. Note the extraluminal collections of gas (*solid black arrows*) within the lesion that are separate from the esophageal lumen (*open black arrow*). **C.** T1-weighted (TR/TE, 674/12) MRI scan also shows a mass (*straight arrows*) in the left side of the mediastinum. Note how the mass is isointense with skeletal muscle. **D.** T2-weighted (2697/80) MRI scan shows how the lesion (*straight arrows*) is markedly hyperintense relative to skeletal muscle. In both **C** and **D**, there is a focal area of signal void (*curved arrows*) caused by extraluminal gas within the tumor. (From Levine MS, Buck JL, Pantongrag-Brown L, et al: Leiomyosarcoma of the esophagus: Radiographic findings in 10 patients. *AJR* 167:27–32, 1996.)

Figure 24-19 Primary malignant melanoma of the esophagus. There is a polypoid mass expanding the lumen of the distal esophagus. This lesion cannot be distinguished from spindle cell carcinoma (see Fig. 24-17) or other rare malignant tumors of the esophagus. (From Yoo CC, Levine MS, McLarney JK, et al: *Primary malignant melanoma of the esophagus: Radiographic findings in seven patients. Radiology* 209:455–459, 1998.)

DIFFERENTIAL DIAGNOSIS

The major consideration in the differential diagnosis of a large polypoid intraluminal mass in the esophagus is spindle cell carcinoma.^{62,63,65} Other unusual tumors of the esophagus that may produce similar findings include leiomyosarcoma, lymphoma, and Kaposi's sarcoma. In contrast, squamous cell carcinoma and adenocarcinoma of the esophagus rarely appear as expansile esophageal masses because these tumors tend to infiltrate and narrow the lumen rather than expand it.

Kaposi's Sarcoma

Kaposi's sarcoma is a multifocal neoplasm of the reticuloendothelial system that is typically manifested by slow-growing cutaneous lesions on the lower extremities. However, a much more aggressive form of Kaposi's sarcoma has been found to develop in patients with AIDS. In studies from the 1980s, more than 30% of AIDS patients in the United States had Kaposi's sarcoma,⁹⁷ and about 50% of patients with Kaposi's sarcoma had gastrointestinal lesions, usually in the stomach or small bowel and occasionally in the esophagus.^{98–100} With the development of more effective medical therapy for the HIV virus to prevent the development of AIDs, however, gastrointestinal

Figure 24-20 Kaposi's sarcoma involving the esophagus. Multiple submucosal masses (arrows) are seen in the esophagus. This patient had additional submucosal lesions elsewhere in the gastrointestinal tract. (Courtesy Robert A. Goren, MD, Philadelphia.)

Kaposi's sarcoma is rarely encountered in modern medical practice.

RADIOGRAPHIC FINDINGS

Esophageal involvement by Kaposi's sarcoma may be manifested on barium studies by a single polypoid mass in the esophagus or by multiple submucosal lesions (Fig. 24-20).^{98,100} When multiple submucosal lesions are present, the differential diagnosis includes lymphoma and leukemia involving the esophagus. Kaposi's sarcoma should be suspected, however, when one or more discrete esophageal lesions are found in AIDS patients with associated skin lesions.

Small Cell Carcinoma

Primary small cell carcinoma of the esophagus is a rare but aggressive malignant tumor characterized by early metastases and a rapidly fatal course. The tumor may be derived from argyrophilic cells or Kulchitsky cells of neuroectodermal origin.^{90,101} Affected individuals typically present with rapidly progressive dysphagia and weight loss.^{102,103} These patients have a dismal prognosis, with an average survival of 6 months

Figure 24-21 Small cell carcinoma of the esophagus. There is a smoothly margined, sessile mass (white arrows) containing a relatively flat central area of ulceration (black arrow) on the right posterolateral wall of the midesophagus below the level of the carina. Squamous cell carcinoma of the esophagus could produce identical findings. (From Levine MS, Pantongrag-Brown L, Buck JL, et al: *Small cell carcinoma of the esophagus: Radiographic findings*. Radiology 199:703–705, 1996.)

or less from the time of diagnosis.¹⁰¹⁻¹⁰³ Because of the likelihood of distant metastases, surgery has been recommended primarily for palliation, whereas combination radiation and chemotherapy has been advocated to improve patient survival.^{101,103,104}

RADIOGRAPHIC FINDINGS

Advanced small cell carcinomas of the esophagus may appear on barium studies as bulky polypoid or fungating masses, sometimes containing areas of ulceration or cavitation.^{62,105,106} Less advanced lesions may be characterized by strikingly similar radiographic findings, appearing as smoothly margined, sessile, centrally ulcerated masses, usually in the midesophagus near the level of the carina (Fig. 24-21).^{107,108} Although this appearance is more likely to be caused by squamous cell carcinoma, it is important to obtain endoscopic biopsy specimens because a preoperative histologic diagnosis of small cell carcinoma may dramatically alter the management of these patients. Rarely, regression of small cell carcinoma has been documented on follow-up barium studies after combination radiation and chemotherapy.¹⁰⁷

Figure 24-22 Leukemic infiltration of the esophagus. This patient has multiple submucosal masses (arrows) in the esophagus caused by leukemic deposits. (Courtesy Sadi R. Antonmattei, MD, Arecibo, Puerto Rico.)

Leukemia

Although rarely diagnosed before death, esophageal involvement by leukemia has been reported at autopsy in 2% to 13% of patients.^{109,110} These leukemic deposits may appear on barium studies as one or more discrete nodular elevations (Fig. 24-22).^{103,105} Coalescent intramural lesions may also be manifested by irregular areas of narrowing in the middle or distal third of the esophagus on barium studies (Fig. 24-23A) and by esophageal wall thickening on CT (Fig. 24-23B).¹¹¹ Rarely, bulky leukemic deposits may appear as polypoid lesions in the esophagus.¹¹² These leukemic implants may undergo marked regression after radiation therapy.¹¹¹ Esophageal symptoms may therefore be palliated by mediastinal irradiation, but the overall prognosis for this disease is unchanged.

Miscellaneous Tumors

Other rare malignant tumors in the esophagus include adenoid cystic carcinoma,^{113,114} chondrosarcoma,¹¹⁵ synovial sarcoma,¹¹⁶ and malignant carcinoid tumor.¹¹⁷ In general, sarcomas tend to be more polypoid than carcinomas, which are more infiltrating lesions. Nevertheless, a definitive diagnosis can be made only on histologic grounds.

Figure 24-23 Leukemic infiltration of the esophagus. **A.** There is irregular narrowing of the midesophagus caused by circumferential leukemic infiltration of the wall. Note a discrete leukemic deposit (arrow) in the distal esophagus. **B.** CT scan just above the level of the stricture shows contrast medium in a dilated lumen (arrow) with leukemic infiltration of the surrounding wall. Mallory-Weiss Tear

PATHOGENESIS

A Mallory-Weiss tear is recognized as a relatively common injury in which a sudden, rapid increase in intraesophageal pressure produces a linear mucosal laceration at or near the

gastric cardia. These tears are usually caused by violent retching or vomiting after an alcoholic binge or by protracted vomiting for any reason.¹⁻³ Less commonly, Mallory-Weiss tears may be caused by prolonged hiccuping or coughing, seizures, straining at stool, childbirth, or blunt abdominal trauma.⁴ Similar injuries may also result from direct laceration of the mucosa by an advancing endoscope or by a sharp foreign body in the esophagus, such as a taco.⁵⁻⁷

CLINICAL FINDINGS

Mallory-Weiss tears account for 5% to 10% of all cases of acute upper gastrointestinal (GI) bleeding.^{8,9} Some patients may have massive hematemesis, but most tears heal spontaneously within 48 to 72 hours, so bleeding is usually self-limited.^{1,4,9} These patients therefore have an excellent prognosis with an overall mortality rate of only about 3%.^{2,4} Although most patients can be managed conservatively, selective intra-arterial infusion of vasopressin, transcatheter embolization, endoscopic electrocoagulation, or surgical repair of the tear may occasionally be required to control bleeding.¹⁰⁻¹³

RADIOGRAPHIC FINDINGS

The vast majority of Mallory-Weiss tears are diagnosed at endoscopy.³ Nevertheless, these mucosal lacerations are occasionally recognized on double-contrast esophagograms as shallow, longitudinally oriented, linear collections of barium in the distal esophagus at or just above the gastroesophageal junction (Fig. 25-1). The radiographic appearance may be indistinguishable from that of a linear ulcer in the distal esophagus caused by reflux esophagitis, but a history of recent vomiting or hematemesis (particularly in alcoholics) should suggest the correct diagnosis.

Esophageal Hematoma

PATHOGENESIS

Most esophageal hematomas are caused by a mucosal laceration or tear in the distal esophagus. If the tear is partially or completely occluded by edema or blood clot, continued hemorrhage may lead to progressive submucosal dissection of blood, producing an intramural hematoma.¹⁴ As with Mallory-Weiss tears, the underlying laceration is usually caused by a sudden increase in intraesophageal pressure resulting from one or more episodes of violent retching or vomiting.^{14,15} Esophageal hematomas may also be caused by esophageal instrumentation or, rarely, by blunt trauma.¹⁶⁻¹⁸ Occasionally, spontaneous hematomas may develop in patients who have impaired hemostasis because of thrombocytopenia, bleeding disorders, or

Figure 25-1 Mallory-Weiss tear. A linear collection of barium (arrow) is visible in the distal esophagus just above the gastroesophageal junction. Although a linear ulcer from reflux esophagitis could produce a similar appearance, the correct diagnosis was suggested by the clinical history. (Courtesy Harvey M. Goldstein, MD, San Antonio, TX.)

anticoagulation.^{19,20} In contrast to traumatic hematomas, which almost always occur as solitary lesions in the distal esophagus, spontaneous hematomas tend to spare the distal esophagus and are more likely to be multifocal.¹⁵

CLINICAL FINDINGS

Patients with esophageal hematomas usually present with severe chest pain, dysphagia, or hematemesis.^{14,20,21} Despite the dramatic clinical findings, most esophageal hematomas resolve in 1 to 2 weeks on conservative treatment without need for surgery.^{14,17,20,21} These lesions should therefore be considered self-limited because they almost never progress to complete transmural perforation.

RADIOGRAPHIC FINDINGS

Esophageal hematomas usually appear on barium studies as solitary submucosal masses in the distal esophagus that are indistinguishable from leiomyomas or other benign intramural lesions (Fig. 25-2).^{14,17-19,22} When a mucosal laceration is present, however, barium may dissect beneath the mucosa into the hematoma. This intramural dissection produces a characteristic double-barreled appearance caused by parallel collections of contrast material in true and false lumens separated by a thin, radiolucent stripe (Fig. 25-3).^{16,23-25} Rarely, a double-barreled

Figure 25-2 Esophageal hematoma. There is a smooth submucosal mass (arrows) in the distal esophagus. The hematoma was caused by a pneumatic dilation procedure for achalasia. The esophagus is narrowed below the hematoma because of the patient's underlying achalasia. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

appearance may also be caused by intramural tracking of barium secondary to Crohn's disease, *Candida* esophagitis, tuberculous esophagitis, or esophageal intramural pseudodiverticulosis.

Esophageal hematomas may be recognized on CT by the presence of a well-defined intramural mass, which sometimes has a tubular appearance, extending a considerable distance along the long axis of the esophagus.^{23,26,27} If the hematoma is acute or subacute, hyperdense areas may be present within the lesion.²⁶

Esophageal Perforation

Esophageal perforation is the most serious and rapidly fatal type of perforation in the GI tract. Untreated thoracic esophageal perforations have a mortality rate of almost 100% because of the fulminant mediastinitis that occurs after esophageal rupture.²⁸ Perforation of the cervical esophagus is a more common but less devastating injury. Early diagnosis of esophageal perforation is important because of the potential need for prompt surgical intervention.

PATHOGENESIS

Instrumentation

Endoscopic procedures are responsible for up to 75% of all esophageal perforations.^{29,30} This complication occurs in about

Figure 25-3 Two examples of intramural dissections with a double-barreled esophagus. **A, B.** The longitudinal intramural tracks (white arrows) are separated from the esophageal lumen by a radiolucent mucosal stripe. Both patients had traumatic dissections that occurred during esophageal instrumentation. The site of the laceration (black arrows) is well seen in **B**. (**A** courtesy Sang Y. Han, MD, Birmingham, AL; **B** courtesy Frank H. Miller, MD, Chicago.)

1 in 3000 patients who undergo endoscopic examinations with modern fiberoptic instruments.³⁰ Most endoscopic perforations involve the piriform sinus or cricopharyngeal region in which the posterior wall of the pharyngoesophageal junction is compressed by the advancing endoscope against the cervical spine.^{29,31} The presence of cervical osteophytes or a pharyngeal diverticulum increases the risk of perforation.³⁰ Unlike cervical esophageal perforations, which often occur in the absence of underlying disease, thoracic esophageal perforations usually result from endoscopic injury at or above esophageal strictures or from therapeutic maneuvers such as variceal sclerotherapy, balloon dilation, bougienage, stent or nasogastric tube placement, and foreign body removal.^{30,32,33} Perforation may also occur after esophageal surgery, usually at the site of a ruptured anastomosis (see Chapter 27).

Foreign Bodies

Most foreign body perforations in adults are caused by impacted animal or fish bones in the hypopharynx that erode through the piriform sinus or cricopharyngeal region. Rarely, foreign body obstructions in the thoracic esophagus also lead to perforation as a result of transmural inflammation and

pressure necrosis at the site of impaction (see later, “[Foreign Body Impaction](#)”). Esophageal perforation may also be caused by accidental or intentional ingestion of caustic agents (see Chapter 21).

Trauma

Penetrating injuries to the esophagus are usually caused by knife or bullet wounds. Because the neck lacks the bony protection afforded by the thorax, these injuries generally involve the cervical esophagus.²⁹ Rarely, blunt trauma to the neck, chest, or abdomen can also lead to pharyngeal or esophageal perforation or transection (see next section).³⁴

Spontaneous Esophageal Perforation (Boerhaave’s Syndrome)

In spontaneous esophageal perforation, a sudden, rapid increase in intraluminal esophageal pressure causes a full-thickness perforation of normal underlying esophageal tissue, with ensuing mediastinitis, sepsis, and shock. Most cases result from violent retching or vomiting, usually after an alcoholic binge.^{35,36} Occasionally, however, spontaneous rupture of the esophagus may result from other causes of increased intraesophageal pressure, such as coughing, weightlifting, childbirth, defecation, seizures, status asthmaticus, and blunt trauma to the chest or abdomen.³⁶

Spontaneous esophageal perforations usually occur as 1- to 4-cm long, vertically oriented, linear tears on the left lateral wall of the distal esophagus just above the gastroesophageal junction.^{35,36} The left side of the distal esophagus is more vulnerable to perforation because of the lack of supporting mediastinal structures in this region, whereas the right side of the distal esophagus is protected by the descending thoracic aorta.^{29,36} Rarely, spontaneous perforation of the upper thoracic esophagus or even the cervical esophagus has been reported.^{37,38}

CLINICAL FINDINGS

Cervical Esophageal Perforation

Most cervical esophageal perforations occur as direct complications of endoscopy. Affected individuals may develop neck pain, dysphagia, or fever. Physical examination often reveals subcutaneous emphysema in the neck as a result of gas escaping from the pharynx into the adjacent soft tissues. If untreated, these patients may develop a retropharyngeal abscess, occasionally leading to sepsis and shock.

Cervical esophageal perforations often heal on conservative management, so most small perforations can be treated nonoperatively. However, larger perforations may require a cervical mediastinotomy and open drainage to prevent abscess formation. These injuries have a much better prognosis than thoracic esophageal perforations, with an overall mortality rate of less than 15%.³⁰

Thoracic Esophageal Perforation

Patients with thoracic esophageal perforation may present with the classic triad of vomiting, substernal chest pain, and subcutaneous emphysema of the chest wall and neck.^{35,39} However, some patients have atypical chest pain referred to the left shoulder or back,³⁵ whereas others have epigastric pain, particularly if the perforation involves the intra-abdominal segment of the esophagus below the diaphragmatic hiatus.⁴⁰ Furthermore, subcutaneous emphysema is not always present on physical examination. As a result, thoracic esophageal perforation can be

mistaken for a variety of acute cardiothoracic or abdominal conditions.^{35,36,39} Signs or symptoms of esophageal perforation can also be masked by treatment with steroids.⁴¹ This clinical confusion sometimes leads to delayed diagnosis and treatment of a life-threatening condition. Unfortunately, the mortality rate for thoracic esophageal perforation approaches 70% by 24 hours.³⁵ Thus, early diagnosis is essential for improving patient survival.

Unlike cervical esophageal perforations, which are often treated conservatively, thoracic esophageal perforations may require an emergent thoracotomy (with surgical closure of the perforation and mediastinal drainage) to prevent the development of mediastinitis, sepsis, and death.⁴² More recently, thoracic esophageal perforations have also been treated successfully with occlusive, removable esophageal stents, obviating the need for surgery.^{43,44} Rarely, thoracic esophageal perforations associated with Boerhaave's syndrome may heal spontaneously without intervention.⁴⁵ Other small, self-contained perforations can sometimes be managed nonoperatively with broad-spectrum antibiotics.³⁰

RADIOGRAPHIC FINDINGS

Plain Radiographs

Cervical Esophageal Perforation. Subcutaneous emphysema or retropharyngeal gas may be visible on anteroposterior or lateral radiographs of the neck within 1 hour after a pharyngeal or cervical esophageal perforation (Fig. 25-4A).²⁹ Subsequently, air may dissect along fascial planes from the neck into the chest, producing pneumomediastinum (see Fig. 25-4A).²⁹ Lateral radiographs of the neck may also demonstrate widening of the prevertebral space, anterior deviation of the trachea and, eventually, a retropharyngeal abscess containing mottled gas or a single air-fluid level.

Thoracic Esophageal Perforation. About 90% of patients with thoracic esophageal perforations have abnormal chest radiographs. The earliest signs of perforation include mediastinal

widening and pneumomediastinum; the latter finding is usually recognized by the presence of radiolucent streaks of gas along the left lateral border of the aortic arch and descending thoracic aorta or along the right lateral border of the ascending aorta and heart (Fig. 25-5A).^{29,35,36} Subsequently, gas in the mediastinum may dissect along fascial planes superiorly to the supraclavicular area, producing subcutaneous emphysema in the neck within several hours of the perforation.³⁶

At least 75% of thoracic esophageal perforations are associated with a pleural effusion or hydropneumothorax.⁴⁶ Distal perforations often result in a sympathetic left pleural effusion or left basilar atelectasis because of irritation of the adjacent pleura and lung parenchyma (see Fig. 25-5A). Pleural effusions may be present within 12 hours of perforation and are occasionally detected before the development of mediastinal or cervical emphysema. If the mediastinal pleura ruptures, gas and fluid may enter the pleural space directly from the mediastinum, producing a hydropneumothorax. Because the distal esophagus directly abuts the mediastinal pleura on the left, 75% of hydropneumothoraces are on the left side, whereas 5% are on the right and 20% are bilateral.³⁵

Rarely, abdominal radiographs may reveal extraluminal collections of gas in the lesser sac or retroperitoneum when the intra-abdominal segment of the distal esophagus is perforated below the diaphragmatic hiatus.^{40,47} Affected individuals may have vague abdominal discomfort without chest pain or other classic signs of esophageal perforation, so the diagnosis is often delayed in these patients. On the other hand, intra-abdominal esophageal perforations have a more benign clinical course, sometimes healing spontaneously on conservative treatment.^{40,47}

Fluoroscopic Examinations

Fluoroscopic esophagography is an excellent study for patients with suspected esophageal perforation. The ideal contrast agent for this examination provides diagnostic information about the site and extent of perforation without posing a risk to the patient. It has been shown experimentally that barium in the

Figure 25-4 Cervical esophageal perforation by traumatic endoscopy.

A. Close-up view from a posteroanterior chest radiograph obtained several hours after the procedure shows extensive subcutaneous emphysema in the neck and associated pneumomediastinum (curved arrow). **B.** Study using water-soluble contrast medium in a steep oblique projection reveals a cervical esophageal perforation (curved black arrow) with contrast medium extending inferiorly in the mediastinum (straight black arrows) behind the esophagus (white arrows). (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 25-5 Spontaneous esophageal perforation (Boerhaave's syndrome). **A.** Posteroanterior chest radiograph shows a right-sided pneumomediastinum (arrows) and left pleural effusion. These findings are highly suggestive of spontaneous esophageal perforation in a patient (particularly an alcoholic) with severe retching or vomiting. **B.** Subsequent study using water-soluble contrast medium confirms the presence of a localized perforation of the left lateral wall of the distal esophagus (black arrows), with extension of the leak laterally and superiorly in the mediastinum (white arrows). (Courtesy Seth N. Glick, MD, Philadelphia.)

Figure 25-6 Importance of using high-density barium for the diagnosis of subtle perforations. **A.** Initial study using water-soluble contrast medium after an esophagogastric anastomosis (arrow), but no definite site of perforation is seen. **B.** Repeat examination performed moments later with high-density barium shows a sealed-off anastomotic perforation (arrows) that was not visible with a water-soluble contrast medium. This case dramatically illustrates how high-density barium should be given to all patients with suspected perforation if the initial study using water-soluble contrast medium fails to demonstrate a leak.

mediastinum is capable of inciting an inflammatory reaction with subsequent granuloma formation and fibrosis,^{48,49} but there is little or no evidence that mediastinal barium causes clinically significant mediastinitis. Although water-soluble contrast agents such as diatrizoate meglumine and diatrizoate sodium (Gastroview, Mallinckrodt, St. Louis) do not produce a detectable histologic response and have no known deleterious effects on the neck, mediastinum, and pleural or peritoneal cavities,^{48,49} water-soluble contrast media are hypertonic agents that are capable of causing severe pulmonary edema if aspirated into the lungs.⁵⁰ On the other hand, barium that extravasates from the esophagus can remain in the mediastinum indefinitely, limiting the radiologist's ability to assess healing on follow-up fluoroscopic examinations. In contrast, water-soluble contrast agents are rapidly absorbed from the mediastinum, so follow-up studies are not compromised by residual extraluminal contrast medium at or near the site of perforation. This is the major rationale for using water-soluble contrast agents as the initial contrast media for the fluoroscopic evaluation of patients with suspected esophageal perforation. Alternatively, some investigators advocate the use of low-osmolality, water-soluble contrast agents such as iohexol (Omnipaque, GE Healthcare, Princeton, NJ) to decrease the risks of aspirated contrast material in the lungs.⁵¹ Others favor the use of barium as the initial contrast agent for patients with suspected esophageal perforation, particularly in patients who are at high risk for aspiration.⁵² When water-soluble contrast agents are used, the pharynx should be carefully observed at fluoroscopy, and the examination should be aborted if significant aspiration is detected during the initial swallow.

A major disadvantage of water-soluble contrast agents is that they are less radiopaque than barium and less adherent to sites of leakage, limiting their ability to depict perforations, particularly small or subtle perforations.⁵³ In various studies, 50% of cervical esophageal perforations and up to 25% of thoracic esophageal perforations were missed on fluoroscopic examinations performed only with water-soluble contrast agents.⁵⁴⁻⁵⁶ When the initial study with water-soluble contrast medium fails to show a leak (Fig. 25-6A), the examination should therefore

immediately be repeated with barium to detect subtle leaks that are more likely to be visualized with a more radiopaque contrast agent (Fig. 25-6B).^{48,49,53,57-59} Although low-density barium is able to visualize 22% to 38% of leaks missed on esophagograms performed with water-soluble contrast agents,^{60,61} high-density barium (i.e., the 250% w/v barium suspension used for double-contrast upper GI examinations) is capable of detecting 50% of leaks that are not visualized with water-soluble contrast agents because of the greater opacity of high-density barium.⁶² Leaks detected only with high-density barium are more likely to be characterized by small, blind-ending tracks or tiny extraluminal collections than those visualized with a water-soluble contrast agent, but patient management is still affected in most cases.⁶² High-density barium should therefore be used to optimize detection of esophageal perforation on fluoroscopic examinations when no leak is initially detected with a water-soluble contrast agent (see Fig. 25-6). In these cases, the downside of retained barium in the mediastinum is more than offset by the earlier diagnosis and treatment of a potentially life-threatening condition.

Esophageal perforations are recognized on esophagography by extravasation of contrast medium from the esophagus into the neck or mediastinum. In patients with spontaneous perforation (Boerhaave's syndrome), contrast medium is usually seen extravasating from the left lateral wall of the distal esophagus into the adjacent mediastinum (see Fig. 25-5B).⁵³ Rarely, spontaneous perforation of the upper thoracic or even the cervical esophagus may also be demonstrated (Fig. 25-7).³⁸

Figure 25-7 Spontaneous perforation of the cervical esophagus after an alcoholic binge. **A.** There is a small, sealed-off perforation (arrows) of the lower cervical esophagus. **B.** Follow-up esophagogram 6 weeks later shows complete healing of the perforation without evidence of a residual leak. (A and B from Isserow JA, Levine MS, Rubesin SE: Spontaneous perforation of the cervical esophagus after an alcoholic binge: Case report. *Can Assoc Radiol J* 49:241–243, 1998.)

Regardless of the site of perforation, a sealed-off leak is usually manifested by a contained extraluminal collection that communicates with the adjacent lumen (see Figs. 25-6B and 25-7A). In contrast, larger perforations may result in free extravasation of contrast medium into the mediastinum, with extension along fascial planes superiorly or inferiorly from the site of perforation (see Figs. 25-4B and 25-5B). In patients with contained perforations, follow-up esophagograms may be obtained to document healing of the leak prior to initiating oral feeding (see Fig. 25-7B).

Computed Tomography

Computed tomography (CT) may also be performed on patients in whom esophageal perforation is suspected on clinical grounds. In such cases, the finding of extraluminal gas, fluid, or contrast material in the mediastinum should be highly suggestive of esophageal perforation (Fig. 25-8).⁶³ Pleural and pericardial fluid collections are other less specific findings.⁶⁴ When a perforation is present, CT also is useful for determining the extent of extraluminal gas and fluid in the mediastinum and for monitoring patients who are treated nonoperatively.⁶³ CT has been shown to be a more sensitive technique than fluoroscopic esophagography for detecting esophageal perforation, most likely because of its ability to show indirect signs of a leak after the leak has sealed off.^{64,65} Conversely, esophagography has a higher specificity than CT, particularly in the setting of previous surgery, in which variable amounts of residual gas and fluid may be present in the mediastinum in the absence of an actual leak.⁶⁵ Another limitation of CT is its frequent inability to locate the exact site of perforation. At our institution, we generally perform fluoroscopic esophagography as the initial examination in patients with suspected esophageal perforation. If the findings on esophagography are equivocal or if esophagography fails to show a leak in patients with a high clinical suspicion for esophageal perforation, CT is performed to increase the sensitivity for detection of leaks.

Figure 25-8 Postsurgical leak into mediastinum on CT. Axial contrast-enhanced CT scan 10 days after an esophagogastrectomy and gastric pull-through shows gas in the proximal end of the intrathoracic stomach (short black arrows) with a focal leak from the anastomotic region (white arrow) into the adjacent mediastinum (long black arrow). (From Lantos JE, Levine MS, Rubesin SE, et al: Comparison between esophagography and chest computed tomography for evaluation of leaks after esophagectomy and gastric pull-through. *J Thorac Imaging* 28:121–128, 2013.)

Foreign Body Impaction

Almost 80% of all pharyngeal or esophageal foreign body impactions occur in children who accidentally or intentionally ingest coins, toys, or other foreign objects.⁶⁶ Foreign body impactions in adults are usually caused by animal or fish bones or inadequately chewed boluses of meat, vegetables, or other bulky food items.^{66,67} Bones tend to lodge in the pharynx near the level of the cricopharyngeus, whereas food usually lodges in the distal esophagus near the gastroesophageal junction.⁶⁸ In contrast to impactions resulting from sharp foreign bodies, food impactions are often caused by underlying esophageal rings or strictures. Although 80% to 90% of foreign bodies in the esophagus pass spontaneously, the remaining 10% to 20% require some form of therapeutic intervention.^{66,69}

CLINICAL FINDINGS

Animal or fish bones tend to lodge in the pharynx, often near the level of the cricopharyngeus.⁶⁸ The patient may complain of pharyngeal dysphagia or of a sensation of a foreign body in the throat. In contrast, food impactions tend to occur in the distal esophagus and are manifested by the sudden onset of substernal chest pain, odynophagia, or dysphagia.⁶⁸ Some patients with distal foreign body impactions have dysphagia that is referred to the pharynx, however, so the subjective site of obstruction is unreliable in determining the level of impaction.

Esophageal perforation occurs in less than 1% of all patients with foreign body impactions.⁶⁷ However, the risk of perforation increases substantially if the impaction persists longer than 24 hours.^{67,70} Perforation results from transmural esophageal inflammation and subsequent pressure necrosis at the site of impaction. The development of mediastinitis may lead to sudden, rapid clinical deterioration, manifested by chest pain, sepsis, and shock.⁷⁰ Rarely, an impacted foreign body can erode through the wall of the esophagus, producing an aorto-esophageal, esophagobronchial, or esophagopericardial fistula (see later, “Fistulas”).

RADIOGRAPHIC FINDINGS

Plain Radiographs

Anteroposterior and lateral radiographs of the neck and chest may occasionally demonstrate bones or other radiopaque foreign bodies in the pharynx or esophagus. Lateral radiographs of the neck are usually more helpful than anteroposterior radiographs in identifying animal or fish bones lodged in the pharynx or cervical esophagus (Fig. 25-9) because these bones are easily obscured by the overlying cervical spine on anteroposterior radiographs. Nevertheless, considerable difficulty may be encountered in differentiating small bone fragments from calcified thyroid or cricoid cartilage.

Fluoroscopic Examinations

In patients with suspected foreign body impaction in the pharynx or cervical esophagus, an early barium swallow may be performed to determine whether a foreign body is present and whether it is causing obstruction. Animal or fish bones in the pharynx or cervical esophagus are easily obscured by intraluminal barium, so they may be difficult to detect on fluoroscopic examinations. However, these foreign bodies are sometimes recognized as linear filling defects in the vallecula,

Figure 25-9 Swallowed pork bone in the neck near the pharyngo-esophageal junction. Note the faintly calcified density (arrows) in the region of the cricopharyngeus on a lateral view of the neck. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

piriform sinus, or cricopharyngeal region (Fig. 25-10). Cotton balls or marshmallows soaked in barium may occasionally be helpful for showing bones lodged in the pharynx or cervical esophagus.

Foreign body impactions in the thoracic esophagus usually result from a large bolus of meat or other food that has lodged above the gastroesophageal junction or above a pathologic area of narrowing, usually a Schatzki ring or peptic stricture.⁶⁶⁻⁶⁸ When an impacted food bolus causes esophageal obstruction, barium studies typically reveal a polypoid defect in the esophagus, with an irregular meniscus caused by barium outlining the superior border of the impacted bolus (Figs. 25-11A and 25-12A). Although the radiographic appearance could be mistaken for an obstructing esophageal carcinoma, the correct diagnosis is almost always apparent from the clinical history. The absence of proximal esophageal dilation in patients with an acute food impaction is also a helpful finding because the esophagus is often dilated in patients with obstructing tumors. In some cases, a small amount of barium may trickle around the impacted food bolus into the distal esophagus, erroneously suggesting a stricture (see Fig. 25-12A). Thus, it may be extremely difficult to ascertain whether the underlying esophagus is normal or abnormal at the time of impaction because the obstructing bolus prevents adequate visualization of the esophagus below this level.

Figure 25-10 Turkey bone in the cervical esophagus. Barium swallow reveals a linear filling defect (arrows) resulting from a bone lodged in the cervical esophagus just below the cricopharynx. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Esophageal perforation is a potential complication of food impaction that usually develops after the impacted bolus has been present longer than 24 hours,⁶⁷ but this complication has been reported as early as 6 hours after the onset of impaction.⁷¹ Esophageal perforation may be manifested by focal extravasation of contrast material into the mediastinum at the site of impaction (Fig. 25-13). Despite the risk of perforation, barium probably should be used as the initial contrast agent in patients with suspected food impaction because these individuals are also at higher risk for aspiration. Alternatively, endoscopy (rather than a barium study) may be performed as the first diagnostic test in this clinical setting because of potential difficulty visualizing and retrieving an impacted food bolus when retained barium is present above the impaction. The fluoroscopist should therefore consult with a gastroenterologist before performing a barium study on these patients.

After the food impaction has been relieved, a follow-up esophagogram may be performed several weeks later to rule out an underlying Schatzki ring or peptic stricture as the cause of the impaction (see Fig. 25-11B).⁶⁶⁻⁶⁸ Rarely, food impactions may be caused by malignant strictures or even by giant thoracic osteophytes or other structures impinging on the esophagus.^{66,72} In other patients, follow-up esophagography may reveal a normal underlying esophagus (see Fig. 25-12B).

Figure 25-11 Distal foreign body obstruction caused by an underlying Schatzki ring. **A.** Initial esophagogram shows barium outlining the superior border of an impacted bolus of meat (arrows) in the distal esophagus with complete obstruction at this level. **B.** Second esophagogram after endoscopic removal of the foreign body shows an underlying Schatzki ring (arrow) as the cause of this impaction.

TREATMENT

When swallowed foreign bodies fail to pass spontaneously, some form of therapeutic intervention is required for their removal. Impacted foreign bodies in the pharynx or esophagus may be removed by endoscopy or the use of a wire basket or Foley catheter balloon under fluoroscopic guidance.^{66-69,73-75} These techniques appear to be safe and effective for extracting blunt foreign bodies from the esophagus. Alternatively, radiologists may attempt to relieve esophageal food impactions by a variety of noninvasive maneuvers. A single dose of 1 mg of intravenous (IV) glucagon sometimes facilitates passage of impacted food in the distal esophagus by relaxing the lower esophageal sphincter.⁷⁶⁻⁷⁸ Administration of gas-forming (i.e., effervescent) agents has also been advocated to distend the esophagus above an obstructing food bolus and facilitate passage of the bolus into the stomach.⁷⁹ Combination therapy with glucagon, an effervescent agent, and water has been shown to relieve esophageal food impactions in about 70% of patients.⁸⁰⁻⁸² Rarely, however, abrupt distention of the obstructed esophagus by a gas-forming agent may cause esophageal perforation,⁸⁰ particularly if the obstructing bolus has been present longer than 24 hours. Because of the potential risk of esophageal perforation, it may be prudent to avoid such maneuvers in all patients with food impactions, instead referring them to endoscopy for removal of the obstructing food bolus.

Figure 25-12 Foreign body obstruction in a normal esophagus. **A.** An impacted meat bolus in the midesophagus appears as a polypoid filling defect (curved black arrow). The incompletely distended esophagus below the impaction (white arrow) could be mistaken for a pathologic area of narrowing. **B.** Repeat esophagogram after removal of the foreign body shows a normal underlying esophagus. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 25-13 Foreign body obstruction with associated perforation. A polypoid defect (curved black arrow) is present in the distal esophagus as a result of an esophageal food impaction. In addition, there is extravasation of contrast medium into a focal collection (small white arrows) in the mediastinum, indicating perforation. Also note the large diverticulum (large white arrow) in the midesophagus. This perforation occurred within 6 hours of the onset of impaction. (From Gougoutas C, Levine MS, Laufer I: *Esophageal food impaction with early perforation*, AJR 171:427–428, 1998.)

Fistulas

ESOPHAGEAL-AIRWAY FISTULA

Most esophageal-airway fistulas result from direct invasion of the tracheobronchial tree by advanced esophageal carcinomas. Tracheoesophageal or esophagobronchial fistulas (usually involving the left main bronchus) have been reported in 5% to 10% of patients with esophageal cancer.^{83,84} They tend to occur after radiation therapy, presumably because radiation-induced tumor necrosis accelerates fistula formation. Other esophageal-airway fistulas may be caused by esophageal instrumentation, endobronchial stents eroding into the esophagus, foreign bodies, blunt or penetrating injuries to the chest or, rarely, perforation of an esophageal diverticulum.^{32,85} Esophagobronchial fistulas may also be caused by tuberculosis, histoplasmosis, or other granulomatous diseases in which necrotic, caseating mediastinal lymph nodes erode into the esophagus and bronchial tree.⁸⁶ Rarely, esophagobronchial fistulas may be congenital.⁸⁷

Patients with esophageal-airway fistulas often present with paroxysmal coughing after ingestion of liquids. Others develop recurrent aspiration pneumonia, hemoptysis, or a productive

cough with particles of food in the sputum. These fistulas may be difficult to differentiate from tracheobronchial aspiration on clinical grounds.

When an esophageal-airway fistula is suspected, the fluoroscopic examination should be performed with barium rather than water-soluble contrast agents because the latter agents are hypotonic and may draw fluid into the lungs, causing severe, potentially fatal pulmonary edema.⁵⁰ Most fistulas are readily demonstrated on barium studies and are found to arise within advanced, infiltrating esophageal carcinomas (Fig. 25-14). Once barium has entered the trachea or bronchi, however, it can be coughed up into the proximal trachea or larynx, so delayed overhead radiographs may erroneously suggest tracheobronchial aspiration. The initial swallow should therefore be performed in a lateral projection (with a video recording of the pharynx) to differentiate a fistula from aspiration.

ESOPHAGOPLEURAL FISTULA

Esophagopleural fistulas are usually caused by previous surgery, esophageal instrumentation, radiation, or advanced esophageal carcinoma directly invading the pleural space.⁸⁸ In contrast to

patients with esophageal-airway fistulas, these individuals may have nonspecific clinical findings such as chest pain, fever, dysphagia, or dyspnea.^{88,89} When an esophagopleural fistula is suspected, the diagnosis can be confirmed by recovery of ingested methylene blue in fluid aspirated during thoracentesis. Nonoperative management of esophagopleural fistulas is associated with mortality rates approaching 100%, whereas surgical repair is associated with mortality rates of about 50%.⁹⁰ Early diagnosis and surgical repair of these fistulas is therefore essential.

Figure 25-14 Esophagobronchial fistula. This fistula (straight arrow) was caused by an advanced, infiltrating esophageal carcinoma (curved arrow). E, Esophagus; T, trachea. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Chest radiographs may reveal a pleural effusion, pneumothorax, or hydropneumothorax on the side of the fistula (Fig. 25-15A).⁸⁸ Pneumomediastinal or mediastinal widening is usually not present on chest radiographs because the mediastinum tends not to be directly involved by the fistula. When an esophagopleural fistula is suspected because of the clinical or plain film findings, a fluoroscopic examination using a water-soluble contrast agent should be performed to confirm the presence of a fistula and determine its precise location (Fig. 25-15B). CT may also be helpful for showing extraluminal collections of contrast medium, gas, or fluid in the pleural space from an esophagopleural fistula or even a gastropleural fistula after an esophagogastricomy and gastric pull-through (Fig. 25-16).⁹¹

Occasionally, surgical disruption of the muscularis propria during a myotomy for achalasia, resection of a leiomyoma, or dissection of malignant tumor adherent to the esophagus may cause eccentric ballooning and thinning of the esophageal wall, resulting in the development of an esophagopleural fistula.⁹² In such cases, CT or esophagography with water-soluble contrast agents may reveal an esophagopleural fistula at the site of esophageal ballooning or thinning (Fig. 25-17).⁹²

AORTOESOPHAGEAL FISTULA

Aortoesophageal fistulas are rare but highly lethal fistulas, usually caused by intraesophageal rupture of an atherosclerotic, syphilitic, or dissecting aneurysm of the descending thoracic aorta.⁹³⁻⁹⁵ Aortoesophageal fistulas may also be caused by a swallowed foreign body, esophageal carcinoma, infected aortic graft, or erosion of an endovascular stent into the esophagus.^{95,96}

Affected patients may initially present with several small sentinel episodes of arterial hematemesis, followed by a symptom-free latent period of hours to weeks and a sudden, final episode of massive hematemesis, exsanguination, and death.⁹³⁻⁹⁵ This latent period has been attributed to a blood clot occluding the fistula, hypotension, and vasoconstriction in response to severe hypovolemia.⁹³ As a result, early diagnosis of an impending aortoesophageal fistula provides the opportunity for definitive, potentially lifesaving surgery with placement of an aortic graft.

Aortoesophageal fistulas should be suspected in patients with arterial hematemesis who have a large atherosclerotic

Figure 25-15 Esophagopleural fistula caused by endoscopic sclerotherapy of esophageal varices. A. Posteroanterior chest radiograph shows a large right pleural effusion. B. Study using water-soluble contrast medium reveals an esophagopleural fistula (black arrow), with contrast medium extending laterally in the right pleural space. There also is extravasated contrast medium in the mediastinum (curved white arrow). (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 25-16 Gastropleural fistula after an esophagogastrectomy and gastric pull-through. Axial contrast-enhanced CT scan 4 days after surgery shows focal breakdown (small white arrows) of the right lateral wall of the intrathoracic stomach (black arrows), with fluid and gas entering a loculated collection (large white arrows) in the right pleural space, indicating the presence of a gastropleural fistula. Note a right-sided chest tube abutting the inferior aspect of this collection. (From Lantos JE, Levine MS, Rubesin SE, et al: Comparison between esophagography and chest computed tomography for evaluation of leaks after esophagectomy and gastric pull-through. *J Thorac Imaging* 28:121–128, 2013.)

Figure 25-17 Esophagopleural fistula secondary to esophageal wall ballooning and thinning after a pneumonectomy. **A.** Single-contrast esophagogram 5 months after a left pneumonectomy shows asymmetric ballooning (arrows) of the left lateral wall of the midesophagus. **B.** CT shows postsurgical changes from the left pneumonectomy with asymmetric ballooning and thinning (arrow) of the left lateral wall of the midesophagus. Note the normal thickness of the right posterolateral wall (arrowheads) of the midesophagus for comparison. **C.** Repeat esophagogram with water-soluble contrast medium 10 months after surgery shows leakage (L) of water-soluble contrast material from the left lateral wall (arrow) of the ballooned midesophagus into the left pleural space, indicating an esophagopleural fistula. **D.** CT also shows an esophagopleural fistula (short arrow) at the site of esophageal wall ballooning and thinning, with oral contrast medium (long arrow) and air in the left pleural space. (From Liu PS, Levine MS, Torigian DA: Esophagopleural fistula secondary to esophageal wall ballooning and thinning after pneumonectomy: Findings on chest CT and esophagography. *AJR* 186:1627–1629, 2006.)

aneurysm of the descending thoracic aorta on chest radiographs.⁹⁵ In such cases, studies using water-soluble contrast agents may reveal extrinsic compression or displacement of the esophagus by the aneurysm but rarely show leakage of contrast medium into the aorta because of the flow dynamics of these structures (Fig. 25-18A).⁹³ When an infected aortic graft has eroded into the esophagus, extravasated contrast medium from the esophagus may occasionally outline the coiled springs of the graft (Fig. 25-18C).^{93,96} The presence of an aorto-esophageal fistula may be confirmed by demonstrating extravasation of contrast medium from the aorta into the esophagus on aortography. The origin of the fistulous track is often occluded by thrombus, however, so aortography may also fail to delineate the actual fistula in these patients (Fig. 25-18B).⁹⁴

ESOPHAGOPERICARDIAL FISTULA

Esophagopericardial fistulas are rare fistulas caused by severe esophagitis, esophageal cancer, swallowed foreign bodies, or surgery.⁹⁷ These fistulas usually lead to the rapid development of severe pericarditis or cardiac tamponade caused by leakage of esophageal contents into the pericardial space. Chest radiographs reveal pneumopericardium or hydropneumopericardium in 25% to 50% of cases.⁹⁷ The diagnosis may be confirmed by having the patient swallow a water-soluble contrast agent to

Figure 25-18 Aortoesophageal fistula caused by an aortic aneurysm. **A.** Initial esophagogram shows anterior displacement and narrowing of the distal esophagus (arrows) by an aneurysm of the descending thoracic aorta. **B.** Subsequent aortogram reveals a saccular aneurysm with intraluminal thrombus (arrows) occluding the origin of the fistula. Although radiographic studies failed to demonstrate the fistula, an aortoesophageal fistula was found at surgery. **C.** Another esophagogram after placement of a Dacron aortic graft shows a recurrent aortoesophageal fistula with extravasated contrast medium from the esophagus outlining the aortic graft (arrows). This fistula was caused by infection of the graft. (From Baron RL, Koehler RE, Gutierrez FR, et al: *Clinical and radiographic manifestations of aortoesophageal fistulas*. *Radiology* 141:599–605, 1981.)

demonstrate the fistulous track or gross filling of the pericardial sac with contrast medium (Fig. 25-19).

Diverticula

Esophageal diverticula may be classified by their location or by their mechanism of formation. The most common locations include the pharyngoesophageal junction (i.e., Zenker's diverticulum) (see Chapter 16), midesophagus, and distal esophagus just above the gastroesophageal junction (i.e., epiphrenic diverticulum). When classified by their mechanism of formation, a pulsion diverticulum develops because of increased intraluminal esophageal pressure from underlying esophageal dysmotility (especially diffuse esophageal spasm), whereas a traction diverticulum develops because of fibrosis in adjacent periesophageal tissues. In the past, many midesophageal diverticula were thought to be traction diverticula caused by scarring from tuberculosis or histoplasmosis in perihilar or subcarinal lymph nodes. This type of diverticulum has decreased considerably in frequency, however, so most midesophageal diverticula are now thought to be of the pulsion variety.⁹⁸

PULSION AND TRACTION DIVERTICULA

Pulsion and traction diverticula are usually incidental findings in the esophagus without clinical significance. When symptoms

are present in patients with one or more pulsion diverticula, they are typically related to the patient's underlying esophageal dysmotility,⁹⁹ but some diverticula that are extremely large may cause symptoms.

Radiographic Findings

Diverticula are readily detected on esophagograms as barium-filled outpouchings from the esophagus. They are best seen in profile, but they may be recognized en face as ring shadows on double-contrast studies. Once a diverticulum has been detected, it should be classified as a pulsion or traction diverticulum. Pulsion diverticula are much more common, usually located in the middle or distal thirds of the esophagus, and often associated with other radiographic evidence of motor dysfunction. They usually have a rounded contour and a wide neck and are frequently multiple (Fig. 25-20). Because they contain no muscle in their wall, they tend to remain filled after the esophagus has emptied of barium (see Fig. 25-20B).

Traction diverticula are usually located in the midesophagus and have a tented or triangular configuration as a result of scarring and retraction from surgery, radiation, or granulomatous disease in the adjacent mediastinum (Fig. 25-21). Traction diverticula typically occur as solitary outpouchings containing all layers of the esophageal wall, including the muscle propria, so they tend to empty when the esophagus collapses. Thus, it is

Figure 25-19 Esophagopericardial fistula caused by a perforated ulcer associated with severe reflux esophagitis. Posteroanterior chest radiograph after oral administration of water-soluble contrast medium reveals a pneumopericardium with free leakage of contrast medium into the pericardial space. Air and contrast medium outline the inner aspect of the pericardial sac. Contrast medium is also faintly seen in a hiatal hernia. (From Cyrlak D, Cohen AJ, Dana ER: Esophagopericardial fistula: Causes and radiographic features. *AJR* 141:177–179, 1983.)

Figure 25-20 Pulsion diverticula. A. Note the smooth contour and wide neck of this pulsion diverticulum (arrow) in the midesophagus. There also is evidence of esophageal dysmotility with weak nonperistaltic contractions more distally. Pulsion diverticula are often associated with esophageal motor dysfunction, particularly diffuse esophageal spasm. **B.** In another patient, the pulsion diverticula remain filled after most of the barium has emptied from the esophagus by peristalsis. Again, note the rounded contour and wide necks of the diverticula. (B from Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

usually possible to distinguish pulsion and traction diverticula on radiologic criteria.

EPIPHRENIC DIVERTICULUM

An epiphrenic diverticulum is an uncommon form of esophageal diverticulum that arises in the distal esophagus, usually within 10 cm from the gastroesophageal junction. It is generally believed to be a pulsion diverticulum caused by diffuse esophageal spasm with markedly increased intraluminal esophageal pressures.^{99,100} In one study, however, diffuse esophageal spasm was found in less than 10% of patients with epiphrenic diverticula,¹⁰¹ so other, as yet undefined, factors may also contribute to the development of these structures. Investigators have also found a significant correlation between the size of the diverticulum and the presence of symptoms (i.e., epiphrenic diverticula >5 cm in diameter are more likely to cause symptoms).¹⁰¹ Thus, the development of symptoms appears to be related primarily to the size of the diverticulum rather than to underlying esophageal dysmotility in these patients.

When an epiphrenic diverticulum fills with food, it may compress the true lumen of the esophagus, causing dysphagia.^{101,102} Food or fluid that accumulates within an epiphrenic diverticulum may also be regurgitated into the esophagus with subsequent reflux symptoms, chest pain, or aspiration.¹⁰¹ Rarely, these diverticula may perforate into the mediastinum or form a fistula to the airway. When symptoms associated with an epiphrenic diverticulum are particularly severe or intractable,

they may necessitate surgical intervention, usually a diverticulectomy and esophagomyotomy.^{103,104}

Radiographic Findings

An epiphrenic diverticulum may be recognized on chest radiographs by the presence of a soft tissue mass (often containing

Figure 25-21 Traction diverticulum. The diverticulum has a pointed or triangular tip (large arrow) as a result of traction and volume loss in the adjacent mediastinum from prior surgery. A surgical clip (small arrow) is seen in the mediastinum. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

an air-fluid level) that mimics a hiatal hernia (Fig. 25-22A and B). Barium studies usually reveal a solitary diverticulum arising from the right side of the distal esophagus (Fig. 25-22C), but epiphrenic diverticula can occasionally be multiple or arise from the left side.¹⁰¹ These structures vary markedly in size, ranging from 1 to 12 cm in greatest diameter.¹⁰¹ When the diverticulum is large enough, barium studies may reveal preferential filling or prolonged retention of barium within the diverticulum, regurgitation of barium or debris from the diverticulum, or compression of the adjacent esophagus by the diverticulum.¹⁰¹

Ectopic Gastric Mucosa

Ectopic gastric mucosa in the esophagus is a common congenital anomaly, with a reported incidence of 4% to 10% at endoscopy.^{105,106} Unlike Barrett's mucosa, ectopic gastric mucosa is unrelated to gastroesophageal reflux disease, and most patients with this finding are asymptomatic. The ectopic patch of gastric mucosa is almost always located in the upper esophagus at or just above the thoracic inlet; hence, it has been called the *inlet patch*.¹⁰⁵

Ectopic gastric mucosa in the esophagus can sometimes be recognized on double-contrast esophagography by a shallow depression with small indentations at its superior and inferior borders (Fig. 25-23).¹⁰⁷⁻¹⁰⁹ These lesions are usually found on the right lateral wall of the upper thoracic esophagus at or near the thoracic inlet.¹⁰⁷⁻¹⁰⁹ Although this depression could be mistaken for ulceration or even an intramural dissection on barium studies,¹⁰⁹ the appearance and location of ectopic gastric mucosa are so characteristic that endoscopy is not warranted in asymptomatic patients. Rarely, affected individuals may develop dysphagia because of associated webs or strictures.^{110,111}

Congenital Esophageal Stenosis

Congenital esophageal stenosis is a rare developmental anomaly caused by defective embryologic separation of the primitive foregut from the respiratory tract, with sequestration of tracheobronchial precursor cells in the esophageal wall.^{112,113} Infants may have a severe form of congenital esophageal stenosis

Figure 25-22 Large epiphrenic diverticulum. **A.** Posteroanterior chest radiograph shows a prominent bulge along the right border of the heart (arrow). **B.** Lateral chest radiograph shows a soft tissue mass (arrows), mimicking the appearance of a hiatal hernia. **C.** A barium study reveals a large epiphrenic diverticulum that remains filled with barium after the esophagus has emptied. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 25-23 Ectopic gastric mucosa in the esophagus. **A.** There is a broad, flat depression (white arrow) on the right lateral wall of the upper esophagus near the thoracic inlet, with a pair of small indentations (black arrows) at both ends of the lesion. Although it could be mistaken for an ulcer, this lesion has the typical appearance and location of ectopic gastric mucosa in the esophagus. **B.** Endoscopy shows a reddish-brown, epithelium-lined depression (arrows) in the upper esophagus characteristic of ectopic gastric mucosa. (From Lee J, Levine MS, Shultz CF: Ectopic gastric mucosa in the oesophagus mimicking ulceration. *Eur J Radiol* 31:97–200, 1997.)

associated with esophageal atresia or tracheoesophageal fistulas,¹¹⁴ but adults may have a mild form of the disease manifested by esophageal strictures.^{115–117}

CLINICAL FINDINGS

Patients with severe forms of congenital esophageal stenosis typically present during infancy with marked dysphagia and vomiting,^{114,118} but patients with milder forms of stenosis may present during adolescence or early adulthood with a long-standing history of intermittent dysphagia, chest pain, and occasional food impactions.^{115–117} For reasons that are unclear, almost all reported cases in adults have been men.^{115–117} Dysphagia in these patients is usually alleviated by endoscopic dilation of the strictures.¹¹⁴

RADIOGRAPHIC FINDINGS

Congenital esophageal stenosis in adults is usually characterized on esophagography by the presence of smooth, tapered strictures in the upper or midesophagus.^{115,116,119,120} The strictures often contain multiple ringlike constrictions, producing a distinctive radiographic appearance on double-contrast esophagograms (Fig. 25-24).¹²⁰ The cause of these ringlike constrictions is uncertain, but they may represent cartilaginous rings similar to those found in the trachea.¹²⁰ Whatever the explanation, the presence of an esophageal stricture with distinctive ringlike constrictions should suggest the diagnosis of congenital esophageal stenosis in the proper clinical setting.

DIFFERENTIAL DIAGNOSIS

Eosinophilic esophagitis is another more common cause of esophageal strictures with distinctive ringlike indentations.¹²¹ The correct diagnosis is often suggested by a history of allergies or asthma or a peripheral eosinophilia in these patients (see Chapter 21). Fixed transverse folds in the distal esophagus associated with longitudinal scarring from reflux esophagitis may also resemble the ringlike indentations of congenital esophageal stenosis, but these transverse folds almost always occur in the distal esophagus in the region of a peptic stricture.¹²² Finally, fine transverse striations may be seen in patients with a so-called feline esophagus, but these transverse striations occur as a transient finding and are not associated with strictures.¹²³

Extrinsic Impressions

NORMAL IMPRESSIONS

A variety of normal structures in the mediastinum, including the heart, aortic arch, and left main bronchus, may cause extrinsic impressions on the esophagus (see Chapter 17). In about 10% of patients, a smooth, gently sloping indentation may also be seen on the right posterolateral wall of the upper thoracic esophagus between the thoracic inlet and aortic arch (Fig. 25-25A).¹²⁴ Correlation with CT has shown that this impression is caused by an unusually prominent right inferior supra-azygous recess of the lung indenting the upper esophagus (Fig. 25-25B).¹²⁴ In patients with this normal anatomic variant,

Figure 25-24 Congenital esophageal stenosis. **A.** There is a mild area of narrowing in the midesophagus with distinctive ringlike indentations (arrows) in the region of the stricture. **B.** Endoscopy also shows ringlike indentations that resemble tracheal rings. (**A** from Luedtke P, Levine MS, Rubesin SE, et al: Radiologic diagnosis of benign esophageal strictures: A pattern approach. *RadioGraphics* 23:897–909, 2003.)

Figure 25-25 Extrinsic impression on the esophagus by a prominent right inferior supra-azygous recess. **A.** There is a smooth, gently sloping indentation (arrows) on the right posterolateral wall of the upper thoracic esophagus between the thoracic inlet and aortic arch. **B.** In the same patient, CT of the chest shows a prominent right inferior supra-azygous recess (r) impinging on the right posterolateral wall of the upper esophagus (arrow). (From Sam JW, Levine MS, Miller WT: The right inferior supra-azygous recess: A cause of upper esophageal pseudomass on double-contrast esophagography. *AJR* 171:1583–1586, 1998.)

the outer wall of the right upper thoracic esophagus is directly apposed to the adjacent lung, producing a smooth demarcation between the soft tissue density of the esophageal wall and the gaseous density of the lung, so the actual thickness of the esophageal wall can be visualized in this region. Because of its frequency, radiologists should be aware of this variant, so it is not mistaken for adenopathy or other masses in the mediastinum, and unnecessary cross-sectional imaging of the chest can be avoided. A narrowed thoracic inlet (in the sagittal dimension) is another anatomic variant that occasionally results in extrinsic compression of the right side of the barium-filled esophagus, erroneously suggesting a mass lesion in this region.¹²⁵ In such patients, however, CT will reveal a narrowed thoracic inlet without evidence of a mass.¹²⁵

ABNORMAL IMPRESSIONS

Abnormal impressions are usually caused by the heart and great vessels. An enlarged left atrium or ventricle may produce a broad impression on the anterior wall of the distal esophagus. In contrast, a tortuous or ectatic descending thoracic aorta may cause a prominent impression on the posterior wall of the distal esophagus near the esophageal hiatus of the diaphragm (Fig. 25-26). In some patients, compression of the distal esophagus by the aorta or an aortic aneurysm may cause dysphagia (i.e., dysphagia aortica).¹²⁶ Similarly, congenital abnormalities of the

Figure 25-26 Esophageal impression (arrow) by an ectatic descending thoracic aorta. The esophagus is narrowed at the level of deviation. (From Levine MS, Gilchrist AM: Esophageal deviation: Pushed or pulled? AJR 149:513–514, 1987.)

great vessels, such as an aberrant subclavian artery and double aortic arch, may compress the esophagus, causing dysphagia (i.e., dysphagia lusoria). The esophagus may also be compressed or displaced by masses in the mediastinum, including substernal thyroid goiters, mediastinal lymphadenopathy, and other benign or malignant neoplasms. CT or magnetic resonance imaging (MRI) of the chest may be performed to determine the cause of the underlying mediastinal mass in these patients.

ESOPHAGEAL RETRACTION

Esophageal deviation may be caused by pulmonary, pleural, or mediastinal scarring with retraction of the esophagus toward the diseased hemithorax (Fig. 25-27). It is usually possible to differentiate this retraction from esophageal displacement by a mediastinal mass, using the radiologic sign illustrated in Figure 25-28.¹²⁷ When the esophagus is displaced or pushed by an extrinsic mass in the mediastinum, it tends to be narrower at this level than above or below the deviated segment (see Figs. 25-26 and 25-28A), whereas the esophagus tends to be wider at this level when it is retracted or pulled by pleuropulmonary scarring (see Figs. 25-27 and 25-28B).¹²⁷ When esophageal retraction is suggested by barium studies, chest radiographs should be obtained to confirm the presence of tuberculosis,

Figure 25-27 Esophageal retraction by pleuropulmonary scarring. The esophagus is deviated to the right (arrow) because of scarring and volume loss from right upper lobe tuberculosis. The esophagus is widened at the level of deviation. This characteristic widening indicates retraction of the esophagus toward the side of pleuropulmonary scarring rather than displacement by a mass on the opposite side.

Figure 25-28 Pushed versus pulled esophagus. **A.** When the esophagus is displaced or pushed by an extrinsic mediastinal mass, it tends to be narrower at this level (arrow) than above or below the deviated segment. **B.** When the esophagus is retracted or pulled by pleuropulmonary scarring and volume loss, however, it tends to be wider at this level (arrow) than above or below the deviated segment. (From Levine MS, Gilchrist AM: *Esophageal deviation: Pushed or pulled?* AJR 149:513–514, 1987.)

radiation damage, postsurgical changes, or other causes of scarring and volume loss in the adjacent hemithorax. It is important to determine whether the esophagus has been pushed or pulled from its normal midline position because esophageal retraction from pleuropulmonary scarring usually occurs as an incidental finding, whereas esophageal displacement by a mediastinal mass may require further investigation with CT or MRI to determine the nature and extent of the mass.

Varices

UPHILL VARICES

Pathophysiology

Uphill varices develop as a result of changes in the venous drainage of the esophagus caused by altered flow dynamics in patients with portal hypertension. Normally, the cervical and upper thoracic esophagus are drained by the supreme intercostal vein, bronchial veins, inferior thyroid vein, and other mediastinal collaterals, the midthoracic esophagus is drained by the azygos and hemiazygos veins, and the distal thoracic esophagus is drained by a periesophageal plexus of veins that communicate distally with the coronary vein. In turn, the coronary vein drains into the splenic vein near its junction with the portal vein or directly into the portal vein. In portal hypertension, however, increased portal venous pressure leads to reversal of venous flow through the coronary vein into a plexus of dilated periesophageal veins that anastomose superiorly with collaterals from the azygos and hemiazygos venous systems. Because the azygos vein drains directly into the superior vena cava, portal venous blood returns to the right side of the heart via the superior vena cava rather than the inferior vena cava, thus bypassing the obstructed portal system.

Clinical Findings

Esophageal varices are important because of the potentially catastrophic consequences of variceal rupture and hemorrhage.

Variceal bleeding occurs in 25% to 35% of patients with cirrhosis, and as many as 30% of these bleeding events are fatal.^{128,129} Although some patients have a major variceal hemorrhage with one or more episodes of massive hematemesis, others have intermittent, low-grade bleeding with melena, guaiac-positive stool, or iron-deficiency anemia. Surprisingly, however, the size and extent of varices correlate poorly with the degree of bleeding.

Radiographic Findings

Chest Radiographs. Esophageal varices may occasionally be manifested on chest radiographs by a retrocardiac posterior mediastinal mass. This finding is caused by dilated periesophageal veins or, less commonly, by dilated azygos or hemiazygos veins.¹³⁰⁻¹³² The mass is usually more obvious on radiographs obtained with the patient in the recumbent position because hydrostatic pressure tends to overcome portal pressure in the upright position, shifting blood flow to more dependent collateral vessels.

Barium Studies. Esophagography has not traditionally been considered a reliable technique for detecting esophageal varices. Some authors have advocated the use of anticholinergic agents to improve visualization of varices by decreasing esophageal peristalsis,^{133,134} but such agents are contraindicated in patients with glaucoma, cardiac disease, or urinary retention.

Whether or not pharmacologic agents are used, optimal demonstration of varices requires meticulous attention to radiographic technique because varices can easily be obscured on overly distended or collapsed views of the esophagus (Fig. 25-29). The examination should be performed with the patient in a recumbent (usually prone right anterior oblique) position, using a high-density barium suspension or paste to increase adherence of barium to the esophageal mucosa. Mucosal relief views of the collapsed esophagus are particularly helpful for demonstrating varices (see Fig. 25-29D). However, peristalsis tends to squeeze blood from the thin-walled varices, rendering them invisible for as long as 15 to 30 seconds (see Fig. 25-29C). The fluoroscopist must therefore wait for the varices to refill before obtaining mucosal relief views. If necessary, the patient should be asked to spit his or her saliva into a basin to avoid initiating a new peristaltic sequence and collapsing the varices again. With optimal technique, esophagography has a sensitivity of almost 90% in detecting esophageal varices.¹³⁵

Because of the underlying venous anatomy, uphill varices tend to be most prominent in the distal third or half of the thoracic esophagus, fading gradually as they ascend to the level of entry of the azygos vein into the superior vena cava. Varices are usually best seen on mucosal relief views, appearing as tortuous or serpiginous longitudinal filling defects in the collapsed or partially collapsed esophagus (see Fig. 25-29D).¹³⁶ Varices may also be seen on double-contrast images when they are etched in white because of trapping of barium between the edge of the varices and adjacent esophageal wall (see Fig. 25-29A). Because varices alternately distend and collapse with peristalsis, respiration, and varying degrees of esophageal distention, they may be observed as a transient finding at fluoroscopy.

Computed Tomography. Esophageal varices may be recognized on CT by a thickened, lobulated esophageal wall

Figure 25-29 Uphill esophageal varices. **A.** Multiple varices are seen on a double-contrast esophagogram. Note how the varices are etched in white. **B.** The varices are obscured by intraluminal barium on a single-contrast image. **C.** The varices also are not visible on a mucosal relief view immediately after a peristaltic stripping wave that has squeezed blood from the dilated veins, causing them to collapse. **D.** However, the varices can be recognized as serpiginous filling defects on another view several seconds after passage of the peristaltic wave. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 25-30 Esophageal varices on CT. Axial contrast-enhanced CT scan shows dense enhancement of the varices (arrows). (Courtesy Robert A. Halvorsen, MD, San Francisco.)

containing round, tubular, or serpentine structures that have homogeneous attenuation and enhance with the administration of IV contrast medium to the same degree as adjacent vessels (Fig. 25-30).¹³⁷⁻¹³⁹ CT may also reveal coronary, paraesophageal, retrogastric, paraumbilical, perisplenic, omental, mesenteric, and abdominal wall varices in patients with portal hypertension.¹³⁹ Occasionally, dilated azygos, hemiazygos, or paraesophageal veins can be mistaken for a posterior mediastinal mass on an unenhanced CT scan.^{132,140} However, the marked degree of enhancement that occurs within these dilated vascular structures after infusion of contrast medium should establish the correct diagnosis.^{132,140}

Angiography. Arteriograms of the celiac artery, selective arteriograms of the superior mesenteric or splenic artery, or, less frequently, portal venograms may be obtained to confirm the presence of uphill varices and determine the nature and extent of underlying venous abnormalities. With portal hypertension, images obtained during the venous phase of the examination usually fail to demonstrate the portal vein because of reversal of blood flow through numerous collateral vessels to bypass the obstructed venous system. In almost all cases, the coronary vein acts to shunt portal blood through a periesophageal plexus of veins, producing uphill varices, which communicate with the azygos venous system and superior vena cava (Fig. 25-31). Delineation of the angiographic anatomy is important when a surgical shunt is contemplated to control variceal bleeding.

Figure 25-31 Angiographic demonstration of esophageal and gastric varices due to portal hypertension. This image from a portal venogram shows cavernous transformation of the portal vein (pv) with reversal of blood flow through the coronary vein (cv) and splenic vein (sv), producing gastric (g) and esophageal (e) varices. (Courtesy Dana R. Burke, MD, Bethesda, MD.)

Differential Diagnosis

A diagnosis of esophageal varices can usually be made on the basis of the radiologic findings. Occasionally, however, submucosal edema and inflammation associated with esophagitis may be manifested by thickened, tortuous longitudinal folds, mimicking the appearance of varices.¹⁴¹ Some esophageal carcinomas may also produce a varicoid appearance because of submucosal spread of tumor (Fig. 25-32).¹⁴²⁻¹⁴⁴ However, varices tend to change in size and shape at fluoroscopy with respiration, peristalsis, and other maneuvers, whereas varicoid tumors have a more fixed, rigid appearance.¹⁴²⁻¹⁴⁴ An abrupt demarcation between the involved segment and adjacent normal esophagus should also favor tumor because uphill varices tend to fade superiorly without an obvious demarcation. Finally, varicoid carcinomas may cause dysphagia, whereas this symptom rarely occurs in patients with varices. Thus, it is usually possible to differentiate these entities on clinical and radiologic grounds.

Treatment

The treatment of bleeding esophageal varices includes IV infusion of vasopressin or somatostatin analogues (e.g., octreotide), esophageal balloon tamponade, portosystemic shunt surgery, the Sugiura procedure, endoscopic sclerotherapy, endoscopic variceal ligation, and transjugular intrahepatic portosystemic shunt (TIPS).^{128,145} The primary aims of therapy are to control active bleeding and prevent rebleeding.

Endoscopic Sclerotherapy. Endoscopic sclerotherapy has emerged as a viable alternative to surgery for controlling variceal bleeding and decreasing the risk of recurrent bleeding with

Figure 25-32 Varicoid carcinoma. Thickened, tortuous folds in the mid-esophagus mimic the appearance of varices. This appearance is caused by submucosal spread of tumor. (Courtesy Akiyoshi Yamada, MD, Tokyo.)

fewer complications than surgery.¹⁴⁶⁻¹⁴⁸ This procedure is performed by paravariceal injection or direct intraluminal injection of varices with a sclerosing solution via a fiberoptic endoscope. The sclerosing agent causes a severe inflammatory reaction and intramural fibrosis with mechanical obliteration of the varices. However, as many as 30% of patients who undergo sclerotherapy develop complications, including mild chemical esophagitis, ulceration, strictures, and esophageal perforation.¹⁴⁹⁻¹⁵²

Contrast studies performed immediately after sclerotherapy may reveal esophageal dysmotility, esophagitis, irregular luminal narrowing, or, rarely, intramural hematomas.^{150,153,154} Mucosal sloughing at the sites of injection may cause ulceration (Fig. 25-33A),^{150,153} whereas transmural necrosis may lead to the development of transverse or longitudinal intramural tracks (Fig. 25-33B), esophagopleural fistulas, or localized esophageal perforation (Fig. 25-33C).^{153,155} Contrast studies performed 30 days or more after sclerotherapy may reveal esophageal strictures of varying length and caliber (Fig. 25-33D).¹⁵²

Sclerosed varices are usually manifested on CT by a thickened esophageal wall with outer high-attenuation and inner low-attenuation regions on contrast-enhanced scans, producing a characteristic laminated appearance.^{156,157} This finding may result from a sclerosant-induced inflammatory reaction, edema, or hemorrhage within the esophageal wall, so normal

Figure 25-33 Complications of endoscopic sclerotherapy of varices. **A.** There is a relatively deep ulcer (arrow) with associated narrowing of the distal esophagus caused by edema and spasm. **B.** This patient has a longitudinal intramural track (arrows) in the distal esophagus. **C.** Another patient has a focal, sealed-off perforation of the distal esophagus with contrast medium entering an extraluminal collection (arrows). **D.** This patient has a long, tapered stricture in the distal esophagus several months after endoscopic sclerotherapy. (**A**, **B**, and **D** from Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

enhancement of varices no longer occurs. CT may also demonstrate a predominantly low-attenuation mediastinal effusion and obliteration of mediastinal fat planes because of an acute paraesophageal reaction after sclerotherapy.¹⁵⁷ In contrast, a mediastinal abscess from esophageal perforation may be manifested on CT by a predominantly high-attenuation mediastinal fluid collection associated with mediastinal or pleural gas.¹⁵⁷ Thus, CT may be helpful in determining the nature and extent of postsclerotherapy complications in these patients.

Endoscopic Variceal Ligation. Endoscopic variceal ligation or banding is another technique for the treatment of bleeding esophageal varices in which the varices are ensnared and ligated with endoscopically placed rubber bands, causing strangulation, sloughing, fibrosis, and eventual obliteration of the varices.¹⁵⁸ It has been shown that variceal ligation is associated not only with lower rebleeding rates than endoscopic sclerotherapy but also with fewer complications.^{159,160} Contrast studies may occasionally be performed after variceal ligation to rule out esophageal perforation. In such cases, the ligated varices may be recognized on esophagography as smooth, rounded filling defects in the distal esophagus that are indistinguishable from small polyps (Fig. 25-34).¹⁶¹ However, the correct diagnosis should be apparent from the clinical history.

DOWNHILL VARICES

Pathophysiology

Because the venous structures draining the cervical and upper thoracic esophagus communicate with the supreme intercostal

vein, bronchial veins, inferior thyroid vein, and other mediastinal collaterals, obstruction of the superior vena cava may lead to reversal of flow through those vessels into esophageal and paraesophageal veins to bypass the obstruction. Because blood flows downward in the dilated esophageal veins, they are called *downhill varices*.¹⁶²

The location and extent of downhill varices depend pathophysiologically on whether the superior vena cava is obstructed above or below the site of entry of the azygos vein into the superior vena cava.^{162,163} If the obstruction occurs above the entry of the azygos vein, downhill varices can return blood from the head and upper extremities via the azygos vein to the superior vena cava below the level of obstruction. As a result, downhill varices are confined to the upper or midthoracic esophagus in these cases. If, however, the obstruction occurs at or below the site of entry of the azygos vein into the superior vena cava, the azygos venous system can no longer be used to bypass the obstruction. In such cases, venous flow continues via downhill varices to the distal esophagus, where the coronary vein diverts blood to the portal vein and inferior vena cava, bypassing the obstructed superior vena cava. Thus, downhill varices of this type may involve the entire thoracic esophagus.

Downhill varices are often caused by bronchogenic carcinoma or, less frequently, by other metastatic tumors or lymphoma in the mediastinum.¹⁶²⁻¹⁶⁴ When the superior vena cava is obstructed by malignant tumor, the patient rarely survives long enough for the varices to extend distally, so they are almost always confined to the upper thoracic esophagus, regardless of whether the obstruction occurs above or below the entry of the

Figure 25-34 Appearance of ligated esophageal varices. A study with water-soluble contrast medium shows several smooth, rounded filling defects (arrows), which could be mistaken for neoplastic lesions in the distal esophagus. These represent banded varices 1 day after endoscopic variceal ligation.

azygos vein into the superior vena cava.¹⁶² Occasionally, however, obstruction of the superior vena cava may be caused by benign lesions such as a substernal goiter or mediastinal fibrosis caused by radiation or histoplasmosis (i.e., sclerosing mediastinitis).^{165,166} In such cases, long-standing obstruction of the superior vena cava at or below the level of entry of the azygos vein may lead to the development of extensive downhill varices involving the entire thoracic esophagus.^{162,166} With greater use of central venous catheters for hyperalimentation or chemotherapy, catheter-induced thrombosis has also been recognized as an increasingly common cause of superior vena cava obstruction.^{167,168} Regardless of the cause of the obstruction, catheter-directed thrombolysis and/or endovascular stents have been shown to be safe and effective alternatives to surgical bypass for treatment of these patients.^{168,169}

Clinical Findings

Obstruction of the superior vena cava results in the superior vena cava syndrome, characterized by facial, periorbital, neck, and bilateral arm swelling and dilated superficial veins over chest wall. Although most patients with downhill varices caused by the superior vena cava syndrome are asymptomatic, affected individuals may occasionally develop hematemesis or

low-grade GI bleeding with melena, guaiac-positive stool, or iron-deficiency anemia.¹⁷⁰ Downhill varices should therefore be suspected in any patient with superior vena cava obstruction who develops signs of upper GI bleeding.

Radiographic Findings

Like uphill varices, downhill varices appear on barium studies as serpiginous longitudinal filling defects in the esophagus (Fig. 25-35).¹⁶⁴ However, they can be differentiated from uphill varices by their location because they are almost always confined to the upper or middle third of the thoracic esophagus, whereas uphill varices are predominantly located in the distal third. As expected, downhill varices are best visualized on mucosal relief views of the collapsed or partially collapsed esophagus with the use of a high-density barium suspension.

When downhill varices are suspected on the basis of barium studies, the patient should be evaluated for other clinical or radiologic signs of superior vena cava obstruction. Chest radiography or CT may reveal obvious widening of the superior mediastinum caused by mediastinal lymphadenopathy (see Fig. 25-35A), tumor, substernal thyroid goiter, or, less commonly, mediastinal fibrosis. Venography may be required to confirm the diagnosis and determine the level and degree of stenosis or obstruction and extent of collateral circulation, particularly if a surgical shunt, catheter-directed thrombolysis, or endovascular stent is contemplated.

Differential Diagnosis

Downhill varices may be confused radiographically with varicoid carcinomas that produce thickened, tortuous folds in the upper or midesophagus as a result of submucosal spread of tumor (see Fig. 25-32).¹⁴²⁻¹⁴⁴ However, downhill varices tend to change in size and shape at fluoroscopy, whereas varicoid tumors have a more fixed appearance and more abrupt, well-defined borders.

IDIOPATHIC VARICES

Rarely, esophageal varices may occur in patients who have no other signs of hepatic cirrhosis, portal hypertension, or superior vena cava obstruction.^{171,172} Because the mechanism of variceal formation is unknown, they have been called *idiopathic varices*. It has been postulated that these varices develop as a result of a congenital weakness in the venous channels of the esophagus.¹⁷¹⁻¹⁷³ Although idiopathic varices are extremely uncommon, they are important because of the risk of variceal bleeding.¹⁷¹

Radiographic Findings

Uphill and downhill varices tend to occur as multiple lesions, but an idiopathic varix usually occurs as a solitary lesion, appearing as a smooth, slightly lobulated submucosal mass in the esophagus (Fig. 25-36A).¹⁷⁴ As a result, the radiographic findings may erroneously suggest a submucosal tumor such as a leiomyoma. However, an idiopathic varix can usually be effaced or even obliterated by esophageal distention (Fig. 25-36B), so images obtained with the patient in an upright or recumbent position with variable esophageal distention should suggest a vascular origin of the lesion.¹⁷⁴ It is important to be aware of this entity, so endoscopists do not inadvertently biopsy a varix without careful visual inspection.

Figure 25-35 Downhill esophageal varices due to superior vena cava obstruction by bronchogenic carcinoma. **A.** Chest radiograph with barium in the esophagus shows thickened, nodular folds in the midesophagus with a normal-appearing esophagus below this level. Note how the superior mediastinum is widened because of adenopathy from metastatic lung cancer. **B.** Mucosal relief view of the esophagus shows prominent downhill varices. **C.** Another view moments later shows obliteration of the varices with greater esophageal distention. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Abnormalities of the Gastroesophageal Junction

MARC S. LEVINE

CHAPTER OUTLINE

Radiographic Technique

Normal Radiographic Appearances

Cardia
Z Line
Mucosal Ring
Muscular Ring

Schatzki Ring

Pathogenesis
Clinical Findings
Radiographic Findings
Differential Diagnosis

Hiatal Hernia

Axial Hiatal Hernia
Paraesophageal Hernia

Carcinoma of the Cardia

Prolapsed Esophagogastric Mucosa

Other Abnormalities

The gastroesophageal junction has traditionally been a difficult area to evaluate on barium studies because the physiologic events associated with swallowing produce a dynamic, constantly changing appearance. The use of complicated, often contradictory terminology to describe normal and abnormal findings at the cardia has also been a source of confusion. Evaluation of the cardia, perhaps more than of any other area in the upper gastrointestinal (GI) tract, requires meticulous attention to radiographic technique. Although rings, strictures, and hernias are best seen on conventional single-contrast barium studies, neoplastic lesions at the cardia are better delineated on double-contrast studies. Thus, radiologists must use different techniques during the fluoroscopic examination to optimally evaluate this area.

Radiographic Technique

The gastric cardia is a notoriously difficult area to examine on single-contrast barium studies. Because of the overlying rib cage, the fundus is not accessible to manual palpation or compression. If the fundus is not fully distended, crowded gastric folds may obscure surface detail in this region. If larger volumes of barium are used to distend the fundus, however, it becomes relatively opaque, so only contour abnormalities can be identified. Because of the inherent limitations of single-contrast barium studies in examining the cardia and fundus,

double-contrast techniques have been used to improve radiographic visualization of this area.

The routine double-contrast esophagogram should include a double-contrast examination of the gastric cardia and fundus.^{1,2} After upright double-contrast views of the esophagus have been obtained, the patient should be placed in the recumbent right lateral position (i.e., right side down) to visualize the gastric cardia directly en face. The cardia should be observed for several seconds and, if it appears normal, a single spot image should be obtained. If the cardia appears abnormal, however, additional spot images should be taken as the patient is rotated farther, so that questionable lesions can be demonstrated both en face and in profile.

After the double-contrast portion of the study has been completed, the patient should be placed in the prone, right anterior oblique position and instructed to rapidly gulp a thin, low-density barium suspension to achieve optimal distention of the distal esophagus. Single-contrast technique is particularly important for evaluating possible rings, strictures, or hernias in this region because upright double-contrast views often fail to produce the degree of distention needed to optimally demonstrate these abnormalities.³ If necessary, a bolster may be placed beneath the patient's upper abdomen to increase intra-abdominal pressure and improve esophageal distention. When a lower esophageal ring is detected, barium tablets or barium-impregnated marshmallows may also be used to help determine the caliber and obstructive potential of the ring and, if the tablet or marshmallow becomes impacted above the ring, to determine whether this impaction reproduces the patient's dysphagia.^{4,5}

Normal Radiographic Appearances

The esophagus is a relatively nondistensible tubular structure with a saccular distal segment that communicates with the stomach. The saccular segment has been termed the *phrenic ampulla* or *vestibule* because it is the "entrance hall" to the stomach.⁶ Manometric studies have shown that the esophageal vestibule corresponds to the location of the lower esophageal sphincter, a 2- to 4-cm in length high-pressure zone just above the gastroesophageal junction that prevents reflux of acid into the esophagus.^{7,8} The vestibule extends inferiorly through the esophageal hiatus of the diaphragm before joining the stomach several centimeters below the hiatus. The short intra-abdominal segment of the esophagus terminates at the gastroesophageal junction or gastric cardia. The left lateral aspect of the cardia is demarcated anatomically by sling fibers that hook around a notch formed between the distal esophagus and gastric fundus (the cardiac incisura). Important anatomic structures in this region that may be recognized on barium studies include the cardia, Z line, and lower esophageal mucosal and muscular

rings. These structures are discussed separately in the following sections.

CARDIA

The gastric cardia is often not visualized on single-contrast barium studies because this region is obscured by barium in the fundus or by overlying gastric rugae. However, the ability to recognize the normal appearances of the cardia has improved dramatically with the use of double-contrast technique. In one study, the normal anatomic landmarks at the cardia were seen on more than 95% of double-contrast examinations but on only 20% of single-contrast examinations.⁹ Thus, double-contrast technique is essential for evaluating this area.

The radiographic appearance of the cardia on double-contrast studies depends on how firmly it is anchored by the surrounding phrenoesophageal membrane to the esophageal hiatus of the diaphragm. When the cardia is well anchored, protrusion of the distal esophagus into the fundus produces a circular elevation containing three or four stellate folds that radiate to a central point at the gastroesophageal junction, also known as the cardiac rosette (Fig. 26-1A).^{9,10} This elevation is demarcated from the adjacent fundus by a curved hooding fold that surrounds it laterally and superiorly. Several longitudinal folds are usually seen extending inferiorly from the cardiac rosette along the posterior wall of the lesser curvature. However, it should be recognized that the cardiac rosette reflects the closed resting state of the lower esophageal sphincter, so this normal

anatomic landmark will be transiently obliterated by relaxation of the lower esophageal sphincter during deglutition.¹⁰

When the cardia is less firmly anchored to the surrounding phrenoesophageal membrane, the cardiac rosette may be visible without an associated protrusion or circular elevation (Fig. 26-1B).¹⁰ With further ligamentous laxity, the rosette itself may vanish and the cardia may be characterized by only a single undulant or crescentic line that traverses the region of the esophageal orifice (Fig. 26-1C).¹⁰ Finally, severe ligamentous laxity may lead to the formation of an axial hiatal hernia, so no cardiac structure is identified below the diaphragm. Instead, gastric folds may converge superiorly to a point several centimeters above the esophageal hiatus (Fig. 26-1D).¹⁰ This finding should therefore suggest an axial hiatal hernia, and a single-contrast esophagogram should be obtained with the patient in a prone position to confirm the presence of a hernia.

Radiologists should be familiar with the various radiographic appearances of the cardia, because malignant tumors involving the cardia may be recognized only by distortion or obliteration of these normal anatomic landmarks (see later, "Carcinoma of the Cardia").

Z LINE

The Z line is an irregular serrated line that demarcates the squamocolumnar mucosal junction.^{6,11} The Z line can sometimes be recognized on double-contrast esophagograms as a thin radiolucent stripe in the distal esophagus with a

Figure 26-1 Normal appearances of the gastric cardia. **A.** This patient has a well-anchored cardia appearing as a circular protrusion with centrally radiating folds (the cardiac rosette). **B.** In another patient, there are stellate folds without a surrounding protrusion because of laxity of the ligaments surrounding the cardia. **C.** Further ligamentous laxity has resulted in obliteration of the cardiac rosette. Instead, this patient has a single crescentic line (arrows) at the cardia. **D.** In another patient with severe ligamentous laxity, gastric folds in a small hiatal hernia are seen converging superiorly toward a point (arrow) several centimeters above the esophageal hiatus of the diaphragm. (From Levine MS: *Radiology of the Esophagus*. Philadelphia: WB Saunders, 1989.)

Figure 26-2 Z line. The normal Z line is seen as a thin, zigzagging, radiolucent stripe (dots) in the distal esophagus near the gastroesophageal junction. (From Levine MS: *Radiology of the Esophagus*. Philadelphia: WB Saunders, 1989.)

characteristic zigzag appearance (Fig. 26-2). Occasionally, the Z line can be mistaken for superficial ulceration associated with reflux esophagitis, particularly if the esophagus is not completely distended. Because the Z line represents the histologic squamocolumnar junction, it is usually located at or near the gastroesophageal junction.

MUCOSAL RING

A lower esophageal mucosal ring is the most common ringlike narrowing found in the distal esophagus. The ring consists of a membranous ridge covered by squamous epithelium superiorly and columnar epithelium inferiorly, so it corresponds histologically to the squamocolumnar junction.^{12,13} This mucosal ring, also known as a B ring, is manifested on barium studies by a thin, weblike area of narrowing at the gastroesophageal junction (Fig. 26-3).^{11,13,14} The ring has smooth, symmetric margins and a height of 2 to 4 mm.^{11,13,14} Mucosal rings with a diameter more than 20 mm rarely cause symptoms.¹¹ If the diameter of the ring is less than 20 mm, however, it may cause dysphagia and might therefore represent a pathologic finding (see later, “Schatzki Ring”).

Lower esophageal mucosal rings are fixed, reproducible structures on barium studies, but the distal esophagus must be adequately distended to visualize these structures. Single-contrast technique with the patient in a prone, right anterior oblique position is particularly well suited for

Figure 26-3 Lower esophageal rings. The mucosal ring appears on a prone single-contrast esophagogram as a thin, weblike constriction (curved arrow) at the gastroesophageal junction above a small hiatal hernia, whereas the muscular ring appears as a relatively broad area of narrowing (straight arrow) near the superior border of the esophageal vestibule. Unlike mucosal rings, muscular rings are often observed as a transient finding at fluoroscopy. (From Levine MS: *Radiology of the Esophagus*. Philadelphia: WB Saunders, 1989.)

demonstrating lower esophageal rings because it is the best technique for achieving optimal distention of the distal esophagus. It has been shown that more than 50% of lower esophageal rings seen on prone single-contrast views of the esophagus are not visualized on the double-contrast phase of the examination.^{3,15} Thus, biphasic studies are required to demonstrate these structures.

MUSCULAR RING

A muscular or contractile ring, also known as an A ring, is a much less common finding in the distal esophagus than a mucosal ring (B ring). Muscular rings are located at the proximal end of the esophageal vestibule near the tubulovesicular junction and are completely covered by squamous epithelium.⁸ Unlike a mucosal ring, which is a fixed anatomic structure, a muscular ring occurs as a transient physiologic phenomenon resulting from active muscular contraction in the distal esophagus in the region of the lower esophageal sphincter.

A muscular ring usually appears on esophagography as a relatively broad, smooth area of tapered narrowing that changes considerably in caliber and configuration during the fluoroscopic examination (see Fig. 26-3).^{7,11,13} Because a muscular ring is caused by active muscular contraction, it may vanish completely with esophageal distention, so it is observed as a

transient finding at fluoroscopy.^{7,11,13} Not infrequently, mucosal and muscular rings are visible during the same examination (see Fig. 26-3). In such cases, the fixed nature of the mucosal ring readily distinguishes this structure from the changing appearance of the muscular ring above.

Schatzki Ring

Although some investigators have used the terms *Schatzki ring* and *lower esophageal ring* interchangeably, Schatzki himself originally described this entity as a pathologically stenotic ring that caused dysphagia.¹⁶ Because most lower esophageal rings do not cause symptoms, they probably should not be called Schatzki rings. Instead, the term should be reserved for symptomatic patients with narrow-caliber rings at the gastroesophageal junction. Thus, the diagnosis of a Schatzki ring is made on the basis of the clinical and radiographic findings.

PATHOGENESIS

The pathogenesis of a Schatzki ring is uncertain. Some investigators favor a congenital origin, but the rarity of symptoms before 50 years of age tends to refute this theory.⁶ Other investigators believe that a Schatzki ring represents an annular, ring-like stricture caused by scarring from reflux esophagitis.^{6,13,17-19} This theory is supported by one study showing that Schatzki rings undergo transformation into true, reflux-induced (peptic) strictures on serial barium studies.¹⁸ Nevertheless, it is difficult to explain the frequent absence of reflux symptoms in these patients, so the data are inconclusive.

CLINICAL FINDINGS

Schatzki rings are typically manifested by episodic dysphagia for solids.^{15,16,20,21} In a study of 332 patients, Schatzki found that lower esophageal rings less than 13 mm in diameter almost always caused dysphagia, whereas rings more than 20 mm in diameter almost never caused dysphagia.²⁰ A statistical analysis of Schatzki's original data 40 years later showed that a 1-mm decrease in ring diameter corresponded to a 46% increase in the likelihood that a patient has dysphagia.²²

Patients with Schatzki rings typically present with episodic dysphagia for solids, sometimes remaining asymptomatic until a large bolus of food lodges above the ring. Because the most frequent offending agent is an inadequately chewed piece of meat, this condition has been described as the *steak house syndrome*.²³ The impacted bolus in the distal esophagus may cause severe chest pain or an uncomfortable sticking sensation behind the lower sternum.²⁴ Resolution of symptoms almost always occurs when the impacted bolus is passed, regurgitated, or removed. Rarely, a prolonged bolus obstruction may lead to esophageal perforation.¹³

Relief from symptoms is sometimes obtained by advising these individuals to eat more slowly and chew their food more carefully. However, some patients with recurrent dysphagia require mechanical disruption or dilation of the ring or, rarely, surgery.^{21,25,26}

RADIOGRAPHIC FINDINGS

A Schatzki ring usually appears on barium studies as a thin (2 to 4 mm in height), weblike constriction (<13 mm in diameter)

Figure 26-4 Schatzki ring. The ring appears on a prone single-contrast esophagogram as a thin, weblike (<13 mm in diameter) constriction (arrow) at the gastroesophageal junction above a hiatal hernia. Note that except for its smaller caliber, it has the same appearance and location as an asymptomatic mucosal ring. This patient presented with dysphagia.

at the gastroesophageal junction (Fig. 26-4).^{11,13-16,20} A hiatal hernia is almost always observed below the level of the ring. Except for its smaller caliber, a Schatzki ring therefore has the same appearance and location as an asymptomatic mucosal ring. Almost all rings less than 13 mm in diameter cause dysphagia,²⁰ so they may be classified as Schatzki rings on the basis of the radiographic findings. Occasionally, however, rings between 13 and 20 mm may also cause symptoms, so the diagnosis of a Schatzki ring in these patients requires some knowledge of the clinical history.

Like other rings in the lower esophagus, Schatzki rings are visualized on barium studies only if the lumen above and below the ring is distended beyond the caliber of the ring. As a result, single-contrast views of the distal esophagus with the patient prone (optimizing distention of the distal esophagus) may demonstrate Schatzki rings that are not visible, even in retrospect, on the double-contrast phase of the examination because of inadequate distention of this region (Fig. 26-5).^{3,15} Conversely, overdistention of a hiatal hernia on prone views can result in overlap of the distal end of the esophagus and proximal end of the hernia, producing a double density of two superimposed, convex collections of barium that obscures the region of the gastroesophageal junction and prevents visualization even of high-grade Schatzki rings (Fig. 26-6A).²⁷ When this overlap

Figure 26-5 Schatzki ring seen only on a prone single-contrast esophagogram.

A. Upright double-contrast view of the distal esophagus shows no evidence of a lower esophageal ring. **B.** However, a prone single-contrast view from the same examination shows a hiatal hernia with an unequivocal Schatzki ring (arrow) above the hernia. Note how the hernia was not visualized on the upright double-contrast image (**A**) because it had fallen below the diaphragm on this view.

Figure 26-6 Overlap phenomenon obscuring Schatzki ring. **A.** Prone single-contrast view of the distal esophagus shows a hiatal hernia without evidence of a lower esophageal ring. However, there is a double density with two superimposed convex collections of barium caused by overlap of the distal end of the esophagus (solid arrows) and the proximal end of the hernia (open arrows). **B.** Repeat view with less distention of the hernia shows a tight Schatzki ring (arrow) when the distal esophagus and adjacent hiatal hernia no longer overlap. (From Hsu WC, MS Levine, Rubesin SE, Overlap phenomenon: A potential pitfall in the radiographic detection of lower esophageal rings, *AJR*, 180, 745-747, 2003.)

phenomenon occurs, additional prone views of the distal esophagus should be obtained when the hiatal hernia is less distended to avoid overlap of the hernia and adjacent distal esophagus, enabling visualization of these rings (Fig. 26-6B).²⁷ If a lower esophageal ring still cannot be detected because of persistent overlap in patients with clinical symptoms of a ring, the patient should be instructed to swallow a barium tablet; if the tablet lodges at the gastroesophageal junction, a Schatzki ring should be strongly suspected, and the patient should undergo endoscopy for further evaluation and a possible dilation procedure. With optimal technique, biphasic esophagography is thought to be even more sensitive than endoscopy for detecting Schatzki rings.¹⁵

DIFFERENTIAL DIAGNOSIS

A Schatzki ring has such a characteristic appearance that the radiographic findings are virtually diagnostic of this entity. Occasionally, however, other abnormalities may produce similar findings. Ringlike peptic strictures constitute as many as 40% of all peptic strictures in the distal esophagus (see Chapter 19).²⁸ These strictures often resemble Schatzki rings, but careful analysis generally shows that they have more tapered, asymmetric margins and are slightly longer (4 to 10 mm) than true Schatzki rings.²⁸ Despite these subtle distinctions, there is probably overlap between the findings of ringlike peptic strictures and Schatzki rings detected on barium studies or endoscopy. Nevertheless, the treatment is similar (a dilation procedure), so this differentiation may be of limited clinical importance.

Esophageal webs are occasionally found in the distal esophagus in the region of a peptic stricture (see Chapter 19).²⁹ These webs can resemble Schatzki rings but are located above the gastroesophageal junction and are almost always associated with peptic strictures, so they can be differentiated from lower esophageal rings on the basis of radiographic findings.²⁹ Rarely, a short, annular esophageal carcinoma can produce a localized constriction that superficially resembles a Schatzki ring. However, the presence of asymmetry, irregularity, and shelflike borders should indicate the need for early endoscopy to rule out a malignant lesion.

Hiatal Hernia

Hiatal hernias are classified as axial or paraesophageal, depending on the relationship of the cardia to the diaphragm and herniated portion of the stomach. The vast majority of hernias are axial, and only a tiny percentage are paraesophageal.³⁰ Despite its rarity, a paraesophageal hernia, unlike an axial hiatal hernia, is considered to be a potentially life-threatening condition because of the risk of volvulus, incarceration, or strangulation of the herniated portion of the stomach.

AXIAL HIATAL HERNIA

Pathogenesis

The phrenoesophageal membrane is a firm elastic structure surrounding the gastroesophageal junction that normally tethers the distal esophagus to the diaphragm and prevents the proximal portion of the stomach from herniating through the esophageal hiatus of the diaphragm into the chest. With aging, however, a lifetime of constant swallowing causes

progressive wear and tear on the phrenoesophageal membrane, with eventual stretching or rupture of the membrane and axial herniation of the proximal portion of the stomach into the chest.^{7,8,30,31} Not surprisingly, the prevalence of axial hiatal hernias increases with age; 60% of older adults in the United States are found to have such hernias on barium studies.³²

Clinical Significance

Considerable controversy exists about the relationship between an axial hiatal hernia and the subsequent development of gastroesophageal reflux and reflux esophagitis. Some investigators believe that the hernia predisposes to gastroesophageal reflux disease, but others believe that an axial hiatal hernia is of doubtful clinical significance when it occurs as an isolated finding without other clinical or radiologic signs of reflux disease.³³⁻³⁵ This subject is discussed in greater detail in Chapter 19.

Radiographic Diagnosis

An axial hiatal hernia may be recognized radiographically when the gastroesophageal junction is located above the esophageal hiatus of the diaphragm. Many of these hernias are sliding hernias that are only present when the patient is recumbent. Single-contrast barium studies with the patient prone are more likely to demonstrate a sliding hiatal hernia than double-contrast studies with the patient upright because the hernia is frequently reduced into the abdomen in the upright position and is more difficult to distend adequately when the patient is standing.³ The patient should therefore be instructed to drink a thin, low-density barium suspension continuously while in the prone, right anterior oblique position for optimal visualization of these structures. In contrast, fixed axial hernias are those in which the hernia persists, even when the patient is upright. This observation is clinically important because patients with a large fixed hernia may have a short esophagus, necessitating an esophageal lengthening procedure such as a Collis gastroplasty at the time of surgery if an antireflux operation is contemplated.

Because a lower esophageal mucosal ring demarcates the anatomic location of the gastroesophageal junction, an axial hiatal hernia may be diagnosed on barium studies obtained with the patient prone when a mucosal ring is observed 2 cm or more above the diaphragmatic hiatus (see Fig. 26-3).¹¹ Even in the absence of a definite mucosal ring, a hiatal hernia can often be recognized by the presence of gastric folds within the hernia (Fig. 26-7). These folds may continue inferiorly through the diaphragmatic hiatus into the abdominal portion of the stomach. Not infrequently, the hernia may be kinked or narrowed at the esophageal hiatus because of extrinsic compression by the surrounding diaphragm at this level. Occasionally, a prominent diagonal notch may also be seen on the left lateral and superior aspect of the hernia because of crossing gastric sling fibers at the cardiac incisura (Fig. 26-8).³⁰

When a moderate-sized or large axial hiatal hernia is present, double-contrast views of the stomach obtained with the patient in an upright or right lateral recumbent position also permit assessment of the mucosa within the hernia for ulcers, neoplasms, or other abnormalities not easily seen on single-contrast images. Ulcers are particularly likely to develop at the hiatal orifice (so-called riding ulcers), where the gastric mucosa is repeatedly exposed to trauma on the ridge riding over the hiatus (Fig. 26-9).³⁶ Occasionally, gastric carcinomas that develop within hiatal hernias may be manifested on double-contrast

Figure 26-7 Axial hiatal hernia. Gastric rugae are seen in the hernia on this prone single-contrast view of the esophagus. (From Levine MS: *Radiology of the Esophagus*. Philadelphia: WB Saunders, 1989.)

Figure 26-8 Large axial hiatal hernia. There is a prominent diagonal notch (arrow) on the superior aspect of the hernia caused by crossing gastric sling fibers at the cardiac incisura. This appearance may erroneously suggest a mixed axial-paraesophageal hernia. (From Levine MS: *Radiology of the Esophagus*. Philadelphia: WB Saunders, 1989.)

studies by polypoid masses or infiltrative lesions with thickened, distorted folds in the hernia.³⁷

When barium studies are performed on patients with giant hiatal hernias (i.e., hernias containing 50% or more of the stomach), the weight of the barium may cause the gastric fundus to droop inferiorly beneath the herniated gastric body, especially in the upright position, producing a distinctive radiographic appearance, also known as a floppy fundus (Fig. 26-10).³⁸ These patients may develop symptoms such as postprandial pain, early satiety, nausea, retching, and vomiting because of the mechanical effect of ingested food and liquids pooling in the floppy fundus or because of subsequent traction on the stomach, which impedes emptying of the hernia.³⁸ Because symptoms result from distortion of the gastric anatomy, these symptoms usually resolve only after surgical repair of the hernia.³⁸

A giant hiatal hernia associated with a floppy fundus can be mistaken on barium studies for an organoaxial gastric volvulus, a potentially life-threatening condition because of the risk of incarceration, strangulation, and infarction of the affected stomach (see Chapter 34).^{36,39,40} In organoaxial gastric volvulus, however, most or all of the stomach herniates above the diaphragm into the lower thorax, with the greater curvature of the stomach rotated above the lesser curvature, producing a so-called upside-down intrathoracic stomach.^{41,42} In contrast, normal anatomic relationships are preserved in patients with a floppy fundus.

Figure 26-9 Hiatal hernia with a riding ulcer. There is a hiatal hernia with a large ulcer (arrow) in the proximal stomach where it traverses the esophageal hiatus of the diaphragm, probably because of repeated trauma to the gastric mucosa at the level of the hiatus.

Figure 26-10 Large axial hiatal hernia with a floppy fundus. **A.** Upright double-contrast view shows a large hiatal hernia, with the gastric fundus (large black arrows) flopping inferiorly beneath the most superior portion of the gas-filled gastric body (large white arrow). Note how there is pooling of barium in the floppy fundus, with a small amount of barium spilling over into the portion of the stomach (small black arrows) that traverses the diaphragm. **B.** Supine oblique view also shows a floppy fundus (large black arrows) inferior to the most superior portion of the gastric body (small black arrow). Note how there is narrowing of the stomach (large white arrow) where it traverses the diaphragm. **C.** Prone oblique view now shows the gastric fundus (black arrows) in its expected location above the intrathoracic portion of the gastric body, so the fundus is no longer flopped inferiorly. In **A**, **B**, and **C**, the small white arrows denote the location of the gastroesophageal junction above the diaphragm. (From Huang SY, Levine MS, Rubesin SE, et al: Large hiatal hernias with a floppy fundus. *AJR* 188:960–964, 2007.)

PARAESOPHAGEAL HERNIA

Pathogenesis

In patients with a paraesophageal hernia, a variable portion of the stomach herniates through the esophageal hiatus of the diaphragm into the chest alongside the distal esophagus while the cardia retains its normal position below the diaphragm. This type of hernia is thought to occur through an unusually large defect in the phrenoesophageal membrane that progressively increases in size with age.³⁶ Paraesophageal hernias therefore develop primarily in older adults (i.e., patients > 70 years of age). Less frequently, these hernias may occur as a result of blunt trauma (e.g., automobile accidents) to the chest or abdomen in patients of any age. Affected individuals may eventually develop a mixed type of axial-paraesophageal hernia if the gastroesophageal junction also rises above the diaphragm.⁴³ Rarely, the entire stomach or a major portion of the stomach herniates through the esophageal hiatus, producing a gastric volvulus (see Chapter 34).

Clinical Significance

Many patients with paraesophageal hernias are asymptomatic, and the hernia is an incidental finding on barium studies performed for other reasons. Unlike axial hernias, paraesophageal hernias are rarely associated with gastroesophageal reflux or reflux esophagitis. As these hernias enlarge, however, twisting or torsion and obstruction at or near the esophageal hiatus of the diaphragm may lead to incarceration, strangulation, infarction, or perforation of the herniated portion of the stomach.^{43–47} Because of these potentially life-threatening complications, some authors believe that surgery is warranted in all patients with paraesophageal hernias (assuming that they are surgical candidates), even when these individuals are asymptomatic.^{48,49} However, conservative management may be appropriate for older patients with paraesophageal hernias who are asymptomatic because of the high risk of surgery in this group. Laparoscopic repair of paraesophageal hernias has also been advocated as a less invasive technique than traditional surgery.⁵⁰

Figure 26-11 Paraesophageal hernia. The gastric fundus has herniated into the chest alongside the distal esophagus, but the gastric cardia (arrow) retains its normal position below the diaphragm. (From Levine MS: *Radiology of the Esophagus*. Philadelphia: WB Saunders, 1989.)

Radiographic Diagnosis

A paraesophageal hernia may be diagnosed on barium studies when the gastric fundus has herniated through the esophageal hiatus of the diaphragm alongside the distal esophagus while the cardia retains its normal position below the diaphragm (Fig. 26-11). In a mixed axial-paraesophageal hernia, however, the cardia has also herniated above the diaphragm into the chest (Fig. 26-12). Occasionally, an axial hiatal hernia can be

Figure 26-12 Mixed axial-paraesophageal hernia. The gastric fundus has herniated into the chest alongside the distal esophagus. In this patient, however, the cardia (arrow) has also herniated above the diaphragm. These are features of a mixed hernia.

mistaken radiographically for a mixed axial-paraesophageal hernia because of a prominent notch on the superior aspect of the hernia that erroneously suggests a paraesophageal component (see Fig. 26-8).³⁰

In patients with a gastric volvulus or upside-down intrathoracic stomach, almost the entire stomach has herniated through the esophageal hiatus into the chest and has assumed an inverted or upside-down configuration (see Chapter 34). Rarely, traction or torsion of the stomach at or near the level of the hiatus may lead to obstruction, strangulation, infarction, or perforation of the intrathoracic stomach.⁴¹ These patients may undergo surgery on an emergent basis without preoperative barium studies because of their rapidly deteriorating clinical condition.

Carcinoma of the Cardia

The clinical and radiographic aspects of carcinoma of the cardia are discussed in detail in Chapter 32. On barium studies, advanced lesions at the cardia may appear as obvious exophytic or infiltrating lesions in the gastric fundus. However, other lesions at the cardia may be recognized only by relatively subtle nodularity, mass effect, or ulceration in this region with distortion, effacement, or obliteration of the normal anatomic landmarks at the cardia (Fig. 26-13).^{9,10,51,52} Because these abnormalities at the cardia are extremely difficult to demonstrate on conventional single-contrast barium studies, double-contrast technique is essential for detecting these lesions at the earliest possible stage.

Figure 26-13 Carcinoma of the gastric cardia. The normal anatomic landmarks at the cardia have been obliterated and replaced by irregular areas of ulceration (arrows) caused by tumor in this region. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Prolapsed Esophagogastric Mucosa

Retrograde or antegrade prolapse of mucosa in the esophago-gastric region may produce a polypoid filling defect in the distal esophagus or gastric fundus (Fig. 26-14A).^{53,54} However, mucosal prolapse usually occurs as a transient phenomenon, so the filling defect intermittently vanishes at fluoroscopy (Fig. 26-14B). The distal esophagus may also invaginate into a sliding hiatal hernia or a hiatal hernia may invaginate into the fundus, producing an apparent mass lesion in this region (Fig. 26-15A).⁵⁵ However, greater distention of the fundus with barium or gas usually displaces the invaginated hernia above the diaphragm and reduces the invaginated distal esophagus, so this lesion is also observed as a transient finding at fluoroscopy (Fig. 26-15B). Thus, it is usually possible to differentiate prolapsed esophagogastric mucosa or invaginated hernias from true polypoid lesions at the cardia.

Other Abnormalities

Other abnormalities occurring at or near the gastroesophageal junction include peptic strictures (see Chapter 19), inflammatory esophagogastric polyps (see Chapter 19), esophageal or gastric varices (see Chapters 25 and 34), primary or secondary achalasia (see Chapters 18 and 24), and squamous cell metastases to the cardia (see Chapter 23).

Figure 26-14 Pseudotumor in the gastric fundus caused by retrograde prolapse of esophagogastric mucosa. **A.** Initial double-contrast view of the stomach shows an apparent polypoid mass (arrows) in the fundus at the expected location of the cardia. **B.** Repeat view as the patient swallows additional barium shows a normal fundus. This pseudotumor was caused by intermittent retrograde prolapse of mucosa in the esophagogastric region.

Figure 26-15 Pseudotumor in the gastric fundus caused by an invaginated hiatal hernia. **A.** An apparent mass lesion (arrows) is seen in the fundus on a double-contrast radiograph. **B.** Moments later, the invaginated hernia (arrows) has risen above the diaphragm, and the pseudotumor is no longer seen.

General Principles

Radiologic evaluation of the postoperative esophagus requires an understanding of the operative procedures and of the normal postoperative radiologic appearances. The purpose of the radiologic examination is to do the following: (1) define the postoperative anatomy and establish a baseline; (2) assess the efficacy of the procedure; and (3) detect complications during the early (<4 weeks after surgery) or late (>4 weeks after surgery) postoperative periods.¹⁻⁵ During the early postoperative period, the most common complications include stasis resulting from adynamic ileus or vagotomy, obstruction resulting from anastomotic edema, and perforation resulting from anastomotic breakdown (Box 27-1).¹⁻⁵ During the late postoperative period, the most common complications include aspiration, gastroesophageal reflux, anastomotic strictures, and recurrent tumor (see Box 27-1).¹⁻⁵

An anastomotic or staple line leak is the most common serious complication of esophageal surgery (Fig. 27-1). Sutures and staples hold less well in the esophagus than elsewhere in the gastrointestinal tract because the esophagus lacks a serosa, esophageal muscle is stringy and soft, and mucosa retracts from the cut esophageal margin because of mobility between the squamous mucosa, fatty submucosa, and muscularis propria.² Leaks also occur at staple lines because of focal ischemia caused by the crush effect of the staple line on viable tissue. A delay in the diagnosis of postoperative perforation leads to increased morbidity and mortality resulting from mediastinitis, abscess formation, or sepsis.⁴ Postoperative patients complaining of cervical, thoracic, or epigastric pain, fever, dysphagia, or respiratory distress may therefore require an emergent esophagogram. At our institution, esophagograms are routinely performed

between the sixth and eighth postoperative days because some patients with esophageal perforation are asymptomatic and others have delayed leaks.⁶ Mildly delayed leaks (postoperative days 7-21) are often caused by ischemia at a staple line.

Edema, hemorrhage, and spasm at an anastomosis are the most common causes of obstruction in the early postoperative period. This obstruction usually resolves within 1 to 2 weeks after surgery. Obstruction may also occur when the viscus used as the esophageal substitute passes through the diaphragm (Fig. 27-2). In the late postoperative period, obstruction is usually caused by a benign stricture related to a healed anastomotic leak, ischemia at the anastomosis, or chronic gastroesophageal reflux. Other patients may have recurrent cancer or a tight diaphragmatic hiatus as the cause of a narrowing.

Esophageal dysmotility, delayed gastric emptying caused by pylorospasm or gastric atony, or diarrhea may be the result of manipulation, damage, or intentional surgical resection of the vagus nerve. Vocal cord paralysis or dysphagia with abnormal motility of the inferior constrictor muscles or proximal esophageal muscles may result from recurrent laryngeal injury.

Any form of esophageal surgery that disrupts the lower esophageal sphincter may result in gastroesophageal reflux. An antireflux procedure may be included as part of the esophago-gastric anastomosis to prevent postoperative gastroesophageal reflux. Complications of postoperative gastroesophageal reflux include aspiration, reflux esophagitis, stricture formation, Barrett's esophagus, and adenocarcinoma arising in Barrett's esophagus.

The thoracic duct may also be damaged during surgery. The thoracic duct passes superiorly, anterior to the spine, between the aorta and azygos vein. At the level of the T5 vertebral body, the thoracic duct crosses behind the esophagus and then continues cranially along the left side of the esophagus. Although uncommon, thoracic duct damage may result in chylothorax or chylous ascites.²

Early postoperative complications may be manifested by a variety of findings on chest and abdominal radiographs. A dilated viscus with air-fluid levels should suggest gastric outlet obstruction when the stomach is used to replace the esophagus. Pneumomediastinum, cervical or subcutaneous emphysema, a widened mediastinum, or a rapidly enlarging pleural effusion should suggest anastomotic breakdown and perforation.⁷ Nevertheless, chest and abdominal radiographs may be normal in patients with perforation.

Depending on the nature of the surgery and status of the patient, the postoperative radiologic examination should be tailored to demonstrate suspected complications. Barium and water-soluble contrast agents each have advantages and disadvantages in evaluating patients during the early postoperative period.⁸⁻¹⁸ This subject is discussed in detail in Chapters 1 and 17. Briefly, water-soluble contrast agents should be used during the early postoperative period to rule out a perforation or anastomotic leak into the mediastinum or pleural space. If no

BOX 27-1 COMPLICATIONS OF ESOPHAGEAL SURGERY**EARLY COMPLICATIONS****Common Complications**

- Anastomotic or staple line leak
- Anastomotic narrowing
- Gastric or duodenal atony
- Aspiration
- Gastroesophageal reflux
- Delayed bypass emptying
- Anastomotic edema
- Anastomotic narrowing
- Gastric or duodenal atony
- Obstruction at diaphragm—pyloric channel obstruction or spasm

Uncommon Complications

- Pneumothorax
- Pneumomediastinum
- Mediastinal hematoma
- Empyema
- Vocal cord paresis
- Chylothorax
- Ischemia of colonic or jejunal bypass
- Splenic injury
- Pancreatitis

LATE COMPLICATIONS**Common Complications**

- Anastomotic stricture
- Aspiration
- Recurrent carcinoma
- Gastroesophageal reflux and its sequelae

Uncommon Complications

- Delayed conduit emptying
- Tracheoesophageal fistula
- Anastomotic or staple line leak

water-soluble contrast medium is seen to extravasate from the esophagus on initial spot images, high-density barium should then be given for a more detailed examination.^{1,19,20} Barium or low-osmolality, water-soluble contrast agents such as iohexol (Omnipaque) may be used as the primary contrast agent if aspiration or an esophageal-airway fistula is suspected.

Gastroesophageal Reflux and Hiatal Hernia

Patients with gastroesophageal reflux may undergo surgery because of intractable reflux esophagitis, peptic strictures, or Barrett's esophagus. With most of these surgical procedures, the crura are dissected, the esophagus is mobilized, the vagus nerves are preserved, the hiatal hernia is reduced, the diaphragm is repaired, and the intra-abdominal esophagus is restored. A variable portion of gastric fundus is usually wrapped around the proximal stomach.^{4,21}

NORMAL POSTOPERATIVE APPEARANCES

In a Nissen fundoplication, the gastric fundus is loosely wrapped 360 degrees around the proximal stomach to create an antireflux valve.²² The Nissen fundoplication wrap normally appears

Figure 27-1 Esophagogastric anastomosis with leak near esophagogastric anastomosis. Spot radiograph centered at the esophagogastric anastomosis shows a 3-cm long track of barium arising from the left anterolateral wall of the anastomosis (*small arrow*). The track extends to the left and is just entering (*large arrow*) a mediastinal drain.

as a 2- to 3-cm fundal mass, with a smooth contour and surface (Fig. 27-3).^{23,24} If the patient drinks barium in a recumbent, steep oblique, or lateral position, the lumen is shown to pass through the center of the fundoplication wrap.²⁵ The smooth symmetric wrap and its consistent relationship with the lumen readily differentiates a fundoplication wrap from a true tumor in the fundus.

In a Belsey Mark IV repair, the gastric fundus is sutured to the intra-abdominal esophagus, creating an acute esophagogastric junction angle (angle of His); a 270-degree fundoplication wrap is then created.^{26,27} The gastric wrap of a Belsey Mark IV repair produces a smaller defect than a Nissen fundoplication.²⁸ Two distinct angles are formed passing through the 270-degree fundoplication.²⁹ The intra-abdominal esophagus has a shallow upper angle where the esophagus, fundus, and diaphragm are sutured together and a lower angle where the stomach is pulled upward toward the esophagus.²⁸

A less than circumferential wrap may be made anteriorly or posteriorly, especially in patients with esophageal dysmotility and poor esophageal clearance. Wraps may be made loosely (Fig. 27-4), especially if the surgery is performed laparoscopically. Knowledge of the exact surgical technique performed is helpful for radiologic interpretation.

COMPLICATIONS

Complications related directly to surgery include pneumothorax and pneumomediastinum. Acute hemorrhage usually arises from the short gastric vessels ligated at surgery or is related to operative injury of the spleen or liver. Instrumental perforation

Figure 27-2 Postoperative obstruction after esophagogastrectomy. There is tapered narrowing of the stomach (large arrow) where it passes through the diaphragm. Below the diaphragm, twisting of the stomach is manifested radiographically by gastric folds (small arrows) radiating toward the area of narrowing. The stomach proximal to the obstruction shows dilation, delayed emptying of barium, and retained debris (open arrow). (From Rubesin SE, Beatty SM: *The postoperative esophagus*. *Semin Roentgenol* 39:401–410, 1994.)

of the esophagus or stomach may not be detected during surgery and may lead to a left upper quadrant abscess. Late esophageal perforation may be caused by ischemia or diathermy injury.^{2,4}

Obstruction

During the early postoperative period, edema of the fundoplication wrap may cause transient dysphagia. This complication may be manifested on esophagograms by a large, smooth fundal mass associated with smooth, tapered narrowing of the intra-abdominal esophagus and delayed emptying of contrast material (Fig. 27-5).²³ The edema usually subsides within 1 to 2 weeks; a follow-up esophagogram demonstrates a much smaller defect in this region because of the normal fundoplication wrap.

Some patients may have persistent narrowing at the fundoplication, causing dysphagia or the so-called gas bloat syndrome, with upper abdominal fullness and an inability to belch after meals.²¹ Patients may also complain of an inability to vomit and increased flatulence. In such cases, esophagograms may demonstrate fixed narrowing of the lumen as a result of a tight fundoplication wrap (Fig. 27-6) or excessive closure of the esophageal hiatus of the diaphragm.^{30,31} It is sometimes

Figure 27-3 Normal Nissen fundoplication. The fundoplication wrap is seen as a smooth-surfaced, well-defined mass (arrows) in the gastric fundus.

difficult to distinguish a persistent reflux-induced distal esophageal stricture from a tight wrap. Examination of the preoperative images is helpful.

Recurrent Hiatal Hernia and Gastroesophageal Reflux

Complete disruption of the fundoplication sutures and crural repair is manifested radiographically by a recurrent hiatal hernia and gastroesophageal reflux, without visualization of the fundoplication wrap (Fig. 27-7).^{32,33} Partial disruption of the fundoplication sutures may be manifested by a partially intact wrap associated with one or more outpouchings from the gastric fundus (Fig. 27-8) or by an hourglass appearance of the stomach as the fundus slips through the fundoplication.^{32,33} An hourglass stomach may also be caused by inappropriate placement of the fundoplication around the gastric body. Finally, disruption of the diaphragmatic sutures (but not the fundoplication sutures) may result in a recurrent hiatal hernia, with continued demonstration of an intact fundoplication wrap (Fig. 27-9).³² A paraesophageal hernia may occur at diaphragmatic repair breakdown (Fig. 27-10).

Benign Strictures

Benign esophageal strictures may be treated by various surgical and nonsurgical procedures, including esophageal bougienage, fluoroscopically controlled balloon dilation, endoscopically

Figure 27-4 Loose fundoplication wrap. The loose fundoplication wrap is filled with barium and is manifested as a white/barium-filled rectangular structure crossing the gastric cardia (white arrows). The wall of the fundoplication wrap is seen as a thick, linear radiolucency (black arrows) adjacent to the rectangular barium collection. (From Rubesin SE, Levine MS: *Postoperative esophagus*. In Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989, pp 267–290.)

Figure 27-5 Postoperative wrap edema. One day after laparoscopic fundoplication wrap surgery, the patient had chest pain and difficulty handling her secretions. A low-magnification radiograph shows a large volume of gas (carbon dioxide) underneath the left and right hemidiaphragms. The esophagus just proximal to the fundoplication is a tight 3 mm in luminal diameter (arrows). The thoracic esophagus is dilated and showed delayed esophageal emptying. One week later, the esophageal obstruction caused by edema of the fundoplication wrap had resolved. The esophageal narrowing increased to about 8 mm.

Figure 27-6 Persistent obstruction by a tight Nissen fundoplication wrap. **A.** Spot radiograph obtained with patient in an erect position shows that the lumen of the stomach is mildly narrowed (measuring ≈ 6 mm in luminal diameter; arrows) by a tight fundoplication wrap (arrows). **B.** Spot radiograph obtained while the patient is drinking in a right anterior oblique position shows a narrowed distal esophagus (thin arrows) and large fundoplication wrap (arrowheads).

Figure 27-7 Breakdown of fundoplication wrap and recurrent hiatal hernia. Multiple gastric outpouchings (open arrows) are seen above the level of the diaphragm (large black arrow). The expected mass of the fundoplication wrap is not present in the gastric fundus. A focal peptic stricture is also seen at the gastroesophageal junction (small black arrow). (From Rubesin SE, Levine MS: *Postoperative esophagus*. In Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989, pp 267–290.)

Figure 27-8 Partial breakdown of fundoplication wrap. The fundal wrap is partially intact (black arrows) but does not encircle the distal esophagus. A small fundal outpouching is present (white arrow). Barium is seen in the distal esophagus because of gastroesophageal reflux.

placed esophageal stents, and esophageal replacement with a gastric tube, jejunal graft, or colonic interposition. The site, extent, and cause of the stricture affect the therapeutic choice. Peroral balloon or endoscopic dilation of strictures under fluoroscopic guidance is an effective alternative to esophageal bougienage.^{34,35} This procedure has a lower risk of perforation and a longer symptom-free interval than esophageal bougienage.^{36–39}

Surgery is usually required for the treatment of lye strictures. Esophageal replacement surgery may also be performed on patients with intractable strictures caused by gastroesophageal reflux disease.

Carcinoma

Because they usually have advanced tumors at the time of diagnosis, patients with esophageal carcinoma continue to have 5-year survival rates of only 5% to 30%, despite advances in radiologic imaging, surgical technique, and treatment with radiation or chemotherapy. Treatment for esophageal carcinoma is primarily palliative, focused on reversing starvation and cachexia by relieving dysphagia and restoring the ability to swallow. Palliation of advanced esophageal cancers can be achieved not only by surgery but also by radiation therapy, esophageal stent placement, and endoscopic laser therapy.

ESOPHAGOGASTRECTOMY

The esophagus can be removed by a transthoracic or a combined transhiatal-cervical approach. Distant metastases and aortic or tracheobronchial invasion by tumor are relative contraindications to surgery, but local extension of tumor and mediastinal adenopathy are not.⁴⁰

Transthoracic Approach

A right-sided thoracotomy and abdominal incision (Ivor-Lewis operation) are performed on many patients with midthoracic esophageal cancers.⁵ A left-sided thoracoabdominal incision is performed on patients with cancers involving the distal esophagus and cardia or lesions that have extensive nodal metastases near the celiac axis or lesser curvature of the stomach. After resection of the diseased esophagus and cardia, the stomach is mobilized on its vascular pedicle and placed in the thorax, with the lesser curvature facing the mediastinum (Fig. 27-11). A vertically oriented portion of the stomach may be removed, so that the stomach becomes tubular and functions as a conduit. An antireflux procedure may also be performed by invaginating the distal esophagus into the stomach. A gastric drainage procedure such as a pyloroplasty or pyloromyotomy is usually performed because the vagus nerves are sacrificed at surgery.

Figure 27-9 Recurrent hiatal hernia resulting from disruption of sutures closing the esophageal hiatus of the diaphragm. A small hiatal hernia (long arrows) lies above the diaphragm. An intact fundoplication wrap (short arrows) is manifest as a radiolucent filling defect in the barium pool within the hernia and as a “mass” surrounding the distal esophagus.

Transhiatal-Transcervical Approach

The stomach can also be used as a palliative bypass organ for advanced esophageal carcinoma, without resorting to a thoracotomy.^{41,42} In such cases, the stomach is brought superiorly through an anterior or posterior mediastinal tunnel into the neck via a combined transcervical-transhiatal approach. The fundus is then anastomosed to the cervical esophagus (and occasionally the pharynx) via a cervical approach. The diseased esophagus can be resected through the hiatal and cervical exposures, or it can be excluded. If the stomach has been placed substernally, the small opening of the thoracic inlet is widened by resecting the medial portion of the clavicle, sternoclavicular joint, and upper portion of the manubrium. A pyloromyotomy or pyloroplasty is performed to facilitate gastric emptying. A temporary feeding jejunostomy tube is usually inserted.

The transthoracic approach allows en bloc resection of the esophagus and local lymph nodes for complete staging and potential cure. Anastomotic or other staple line leaks in the middle mediastinum, however, are serious complications. The transhiatal approach allows removal of some, but not all cervical, intrathoracic, and intra-abdominal lymph nodes. A complete mediastinal lymph node exploration for staging or cure is not possible, but anastomotic leaks into the neck with the transhiatal approach are less serious than leaks into the mediastinum with the transthoracic approach. Neverthe-

Figure 27-10 Paraesophageal herniation of gastric fundus after breakdown of diaphragmatic repair. Low magnification image demonstrating a large paraesophageal herniation of the gastric fundus (PH) above the left hemidiaphragm (arrow). The hernia is next to the distal esophagus (E).

less, the two techniques have about the same success rate for cure.⁵

Complications

The most common complications during the early postoperative period include anastomotic leaks, obstruction, gastric atony and dilation, and aspiration into the larynx. A study using water-soluble contrast medium (followed by high-density barium if there is no evidence of a leak²⁰) is usually performed within 7 to 10 days after surgery to rule out a leak at the esophagogastric anastomosis (see Fig. 27-1), at the line of creation of the gastric tube, and at the pyloroplasty. Leaks along the vertical staple line of the gastric tube may be caused by ischemia. These leaks may appear more than 7 days after surgery. Surgical drains may migrate through leaks near the esophagogastric anastomosis or along the gastric staple line.⁴³ Surgical drains may also enter a viscus by pressure necrosis or be inappropriately placed in a viscus at surgery or at a later intervention. Mechanical obstruction may occur at the esophagogastric anastomosis or pylorus (Fig. 27-12) because of edema, hemorrhage, or leak. Mechanical obstruction may also occur at the distal end of the intrathoracic portion of the stomach because of gastric volvulus or extrinsic compression by the diaphragm. Pancreatitis may rarely develop because the duodenum is freed from the pancreatic head to allow the stomach to be pulled superiorly into the chest.²

The most common complications during the late postoperative period include gastroesophageal reflux and its sequelae,

Figure 27-11 Transthoracic esophagogastrectomy. The stomach (S) has been pulled into the right hemithorax. There is a small contained leak (thick white arrow) at the esophagogastric anastomosis. There is no obstruction as the stomach passes through the diaphragm (black arrow). A mediastinal drain (thin white arrow) is present.

anastomotic strictures, fistulas, and recurrent tumor.⁴⁰ Acute gastroesophageal reflux may result in aspiration pneumonia. Chronic gastroesophageal reflux may lead to reflux esophagitis (Fig. 27-13), peptic strictures (Fig. 27-14), Barrett's esophagus and, eventually, esophageal adenocarcinoma. Healing of anastomotic leaks may result in benign anastomotic strictures. Long-standing anastomotic leaks may result in fistulas to the tracheobronchial tree, pleura, or directly into the lungs (Fig. 27-15). Although recurrent tumor in the mediastinum is best demonstrated by computed tomography (CT) or magnetic resonance imaging (MRI), barium studies may reveal a smooth or spiculated area of extrinsic mass effect on the mediastinal border of the stomach (Fig. 27-16).^{40,44} Recurrent esophageal carcinoma may also be demonstrated by barium studies as a focal mucosal nodularity, nodular mass, or nodular stricture in the distalmost remaining esophagus or at the esophagogastric anastomosis (Fig. 27-17). Any suspicious area should be further evaluated by endoscopy and biopsy. Delayed perforations may occasionally be caused by a recurrent mediastinal tumor or mediastinal irradiation.

Several complications may be related to esophageal exclusion if the diseased esophagus has been bypassed but not resected. If the native esophagus is disrupted, a left subphrenic abscess may develop. The excluded esophagus may also form a posterior mediastinal mucocele.⁴⁵ These mucocoeles may become infected or compress the tracheobronchial tree. Symptoms may also be

Figure 27-12 Obstruction at pylorus after pyloroplasty performed during esophagogastrectomy. There is smooth symmetric narrowing of the pylorus (arrow). Obstruction was manifested fluoroscopically by delayed gastric emptying and radiographically by a barium-fluid-air level in the stomach, indicating retained fluid, rather than the normally expected barium-air level. (From Rubesin SE, Beatty SM: *The postoperative esophagus*. *Semin Roentgenol* 39:401–410, 1994.)

caused by gastroesophageal reflux into the excluded esophagus. Carcinoma may develop in an esophagus bypassed for a lye stricture.⁴⁵

COLONIC INTERPOSITION, JEJUNAL INTERPOSITION, AND FREE JEJUNAL GRAFT

Various segments of the colon and jejunum may be used to bypass severe peptic strictures, caustic strictures, or inoperable esophageal cancers. When colonic interposition is performed, the right or transverse colon is placed in an isoperistaltic direction (Fig. 27-18), whereas the left colon is placed in an isoperistaltic or antiperistaltic direction.⁴⁶ If the colon is placed in the anterior mediastinum, the cologastric anastomosis is usually located on the anterior wall of the stomach.⁴⁶ If the colon is placed in the posterior mediastinum, however, the cologastric anastomosis is located on the posterior wall of the upper stomach.⁴⁶ A vagotomy and pyloroplasty are also performed. A preoperative barium enema may be done to rule out significant colonic disease before surgery. A preoperative angiogram may also be obtained to demonstrate the vascular anatomy of the colon and rule out vascular disease, particularly in patients with suspected atherosclerosis.⁴⁷

Colonic interposition is a procedure performed when the stomach cannot be used for esophageal replacement—for example, in patients with prior gastric surgery. Colonic interposition is associated with much higher morbidity and mortality rates than esophagogastrectomy. Anastomotic leaks occur in 25% to 40% of patients⁴⁰ and are usually located at the proximal anastomosis, leading to abscess and stricture formation

Figure 27-13 Esophagogastric anastomosis with reflux esophagitis. Numerous confluent plaques and pseudomembranes (*open arrow*) are seen on the esophageal mucosa above the esophagogastric junction (*solid arrow*). Free gastroesophageal reflux was seen at fluoroscopy.

Figure 27-14 Esophagogastric anastomosis with peptic stricture. An 8 mm in luminal diameter, short, asymmetric narrowing (*arrows*) is seen at and just above the esophagogastric anastomosis. This region was wider on the immediate postoperative study.

Figure 27-15 Fistula from postoperative stomach extending into the right lung. **A.** Spot radiograph centered near the esophagogastric anastomosis (*black arrows*) shows a fistula arising at a 3-mm diameter hole in the proximal stomach (*thick white arrow*) at its staple line. The leak fills subsegmental bronchi (*thin white arrows*). **B.** Spot radiograph obtained after a metallic stent (*black arrows*) was placed. Barium goes around and through the stent. Barium around the outside of the stent fills the fistula (*white arrow*).

Figure 27-16 Recurrent mediastinal tumor after esophagogastrectomy. **A.** A large lobulated mass (short arrows) invades the postoperative stomach just below the esophagogastric anastomosis (long arrow). **B.** Axial image from an unenhanced CT scan shows a large mass (m) invading the posterior wall of the trachea (black arrows) and narrowing and compressing the pulled-through stomach (white arrow).

Figure 27-17 Recurrent esophageal cancer at esophagogastric anastomosis. Spot radiograph shows a plaquelike elevation (thin arrows) and two small submucosa-appearing masses (thick arrows) just above the narrowed esophagogastric anastomosis (open arrow).

Figure 27-18 Normal colonic interposition. **A.** There is an isoperistaltic right colonic interposition with anastomosis of the terminal ileum (i) to the cervical esophagus. Mild narrowing of the colon is seen where it passes through the diaphragm (arrow). **B.** The ascending colon (ac) is anastomosed to the lesser curvature of the stomach. C, cecum; S, stomach. (From Rubesin SE, Levine MS: *Postoperative esophagus*. In Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989, pp 267–290.)

Figure 27-19 Colonic interposition with stricture formation after an anastomotic leak at the esophagocolonic anastomosis. A tight stricture (open arrow) is present at the anastomosis between the dilated esophagus (E) and collapsed colon (C). A short, blind-ending track (solid arrow) is seen at the site of a prior anastomotic leak. (From Rubesin SE, Levine MS: *Postoperative esophagus*. In Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989, pp 267–290.)

(Fig. 27-19).^{47,48} Other postoperative complications include anastomotic edema and obstruction, chylothorax, mediastinal hematoma or abscess, empyema, and intra-abdominal abscess.⁴⁷ Ischemia of the transposed colon may be manifested radiographically by spasm, ulceration, loss of haustration, or a nodular mucosa.⁴⁸ Occasionally, during the early postoperative period, the mucosal folds in the interposed transverse colon may resemble jejunal folds, but this finding disappears after 1 to 3 months.⁴⁶

Stricture formation at the proximal anastomosis is the most common late postoperative complication, occurring in 20% to 40% of patients (see Fig. 27-19).⁴⁶⁻⁴⁸ Chronic ischemia can result in short or long stricture in other segments of the colonic interposition.⁴⁹ The transposed colon may also become dilated and redundant, leading to the development of delayed graft emptying, with bloating, pain, and dysphagia. Other late complications include diverticulitis or carcinoma of the transposed colon, coloesophageal reflux, colobronchial fistulas, gastric outlet obstruction, and small bowel obstruction within the transverse mesocolon defect created at the time of surgery.⁵⁰

PALLIATIVE INTUBATION

Palliative placement of an esophageal stent may be performed to allow oral feeding through advanced obstructing esophageal cancers or to obturate malignant tracheoesophageal fistulas. The use of expandable intraesophageal metallic stents (Fig. 27-20) has replaced the use of plastic tubes (e.g., Celestin tubes).⁵⁰⁻⁵⁶ These metallic stents may be placed endoscopically, surgically, or fluoroscopically. A study using water-soluble contrast medium is performed after stent placement to evaluate stent position and patency and rule out esophageal perforation. The stent should be fixed in position, with its upper tip proximal to the tumor and its lower tip distal to the tumor.

Figure 27-20 Stent placement for squamous cell carcinoma of the right lung invading the esophagus. **A.** Spot radiograph of the right upper mediastinum with the patient in a right posterior oblique position shows a 10-cm long, broad-based extrinsic mass impression on the posterior wall of the esophagus (arrows). **B.** Spot radiograph obtained 3 months later, after radiation therapy, shows less extrinsic mass impression. However, a fistula (arrow) from tumor at the carina invading the esophagus has now formed. Bronchi and the trachea are filled with barium. Presumptively, necrosis of the tumor after radiation therapy has contributed to the fistula formation. A stent is also present in the right mainstem bronchus. **C.** Spot radiograph obtained after esophageal stent placement shows barium going through the uncovered portion of the stent to surround the stent (short arrows). This barium eventually goes into the tracheoesophageal fistula (long arrow). The stent in the right mainstem bronchus is identified (open arrow).

Contrast medium should flow easily through the lumen of the stent.

Esophageal perforation is the most serious complication.^{51,54,57} Obstruction of the stent may be caused by kinking of the stent or luminal obstruction resulting from mucosal prolapse, epithelial hyperplasia, food impaction, or residual or recurrent tumor.^{51,57-59} Reflux of gastric contents through the stent may lead to reflux esophagitis or aspiration pneumonia.^{60,61} Reflux through a stent is such a common problem that stents with antireflux mechanisms have been designed.⁶² Passage of food or liquid around the outside of the stent's proximal margin or reflux of gastric contents around the stent's distal margin may fill a tracheoesophageal fistula (see Fig. 20C) or leak. Metallic stents may initially be malpositioned, or they can migrate.⁴⁵ Rarely, a stent may cause pressure necrosis of the esophageal wall, resulting in a mediastinal leak or aorto-esophageal fistula. Ulceration of the esophagus or stomach may also occur.

Achalasia

Neither medical therapy nor surgery can correct the abnormal esophageal motility and lower esophageal sphincter dysfunction that occur in patients with achalasia. The two major forms of therapy, pneumatic dilation and cardiomyotomy, are both

aimed at improving esophageal emptying by disrupting the high-pressure LES. Intramuscular injection of botulinum toxin has also been used for the treatment of achalasia.

PNEUMATIC DILATION

The most serious complication of pneumatic dilation is lower esophageal perforation, occurring in 1% to 4% of patients.⁶³ Although the presence of chest pain or fever after the procedure should suggest this complication, some patients may have clinically silent or delayed perforations.⁶⁴ A study using water-soluble contrast medium should therefore be performed after pneumatic dilation to rule out a perforation, regardless of the patient's symptoms.^{65,66} If no perforation is seen with water-soluble contrast medium, high-density barium should be given to demonstrate greater anatomic detail and subtle leaks. Perforations usually occur on the left posterolateral wall of the distal esophagus, just above the diaphragm. Some patients may have small, sealed-off perforations that resemble intramural dissections, whereas others may have free perforations into the mediastinum or pleural space.^{67,68} Increasing symptoms during the early postoperative period may necessitate a repeat esophagogram to demonstrate a delayed perforation or perforation that was not initially visualized because of edema and spasm at the dilation site. In addition, edema and

spasm at the gastroesophageal junction may lead to delayed esophageal emptying, despite adequate disruption of the lower esophageal sphincter fibers. Thus, the radiographic appearance immediately after dilation is a poor predictor of the efficacy of the procedure.⁶⁶

CARDIOMYOTOMY

A cardiomyotomy, or Heller myotomy, is an effective form of therapy for patients with untreated achalasia or achalasia that is unresponsive to bougienage, Botox therapy, or pneumatic dilation. The procedure is performed using an open or laparoscopic technique. During myotomy, the LES fibers are surgically divided, thereby disrupting the sphincter. Some surgeons perform a concomitant antireflux procedure. After cardiomyotomy, there should be free flow of contrast medium from the esophagus into the stomach, with decreased esophageal dilation and absence of the beaklike narrowing of the esophagogastric region associated with achalasia.⁶⁹ In about 50% of cases, there is eccentric ballooning of the esophagus at the site of Heller myotomy (Fig. 27-21).⁷⁰ The most common early postoperative complication is perforation of the distal esophagus.⁷¹ Persistent dysphagia during the late postoperative period may indicate an incomplete myotomy or tight fundoplication wrap. Conversely, postoperative gastroesophageal reflux, reflux esophagitis, and peptic strictures may indicate the need for an antireflux procedure.

Varices

Endoscopic sclerotherapy or variceal banding, transjugular intrahepatic portosystemic shunts, portosystemic shunt surgery, and esophageal devascularization procedures are the major forms of therapy for esophageal varices. Endoscopic sclerotherapy and variceal banding are discussed in Chapter 25.

Figure 27-21 Ballooning of the distal esophagus after cardiomyotomy for achalasia. There is eccentric outpouching or ballooning of the distal esophageal wall at the cardiomyotomy site (open arrows). The gastroesophageal junction (solid arrow) is widely patent. (From Rubesin SE, Levine MS: *Postoperative esophagus*. In Levine MS: *Radiology of the Esophagus*. TABLE
28-1

Ulceration

Cause	Radiographic Findings	Distribution	Comments
COMMON			
Reflux esophagitis	Shallow, punctate, or linear ulcers; deep ulcers less common	Distal	Reflux symptoms, hiatal hernia, and/or gastroesophageal reflux
<i>Candida</i> esophagitis	Ulcers associated with diffuse plaque formation ("shaggy" esophagus)	Variable	Odynophagia in immunocompromised (usually AIDS) patients
Herpes esophagitis	Discrete superficial ulcers	Middle or distal	Odynophagia in immunocompromised patients; occasionally in healthy patients
Drug-induced esophagitis	Discrete superficial ulcers; occasionally giant, flat ulcers	Midesophagus near aortic arch or left main bronchus	Odynophagia in patients taking oral medications (e.g., doxycycline or tetracycline)
UNCOMMON			
Radiation esophagitis	Superficial or deep ulcers	Conform to radiation portal	History of radiation therapy
Caustic esophagitis	Superficial or deep ulcers	Variable	History of caustic ingestion
Tuberculous esophagitis	Superficial or deep ulcers	Variable	History of pulmonary tuberculosis or AIDS
Cytomegalovirus esophagitis	One or more giant, flat ulcers	Variable	AIDS patients with odynophagia
HIV esophagitis	One or more giant, flat ulcers	Variable	HIV-positive or AIDS patients with odynophagia
Crohn's disease	Aphthoid ulcers	Variable	Advanced Crohn's disease in small bowel or colon
Nasogastric intubation	Shallow ulcers or giant, flat ulcers	Distal	History of intubation
Alkaline reflux esophagitis	Superficial or deep ulcers	Distal	Partial or total gastrectomy
Behçet's disease	Superficial ulcers	Variable	Oral and genital ulcers and ocular inflammation
Epidermolysis bullosa dystrophica	Superficial ulcers or bullae	Variable	Skin disease
Benign mucous membrane pemphigoid	Superficial ulcers or bullae	Variable	Skin disease

TABLE
28-2

Mucosal Nodularity

Cause	Radiographic Findings	Distribution	Comments
COMMON			
Reflux esophagitis	Nodular or granular mucosa (nodules poorly defined)	Distal third or half of thoracic esophagus	Reflux symptoms, hiatal hernia, and/or gastroesophageal reflux
<i>Candida</i> esophagitis	Discrete plaques	Localized or diffuse	Odynophagia in immunocompromised patients
Glycogenic acanthosis	Nodules or plaques	Localized or diffuse	Asymptomatic
UNCOMMON			
Barrett's esophagus	Reticular pattern	Localized	Often adjacent to distal aspect of midesophageal stricture
Radiation esophagitis	Granular mucosa and decreased distensibility	Conforms to radiation portal	Temporal relationship to radiation therapy
Superficial spreading carcinoma	Poorly defined, coalescent nodules or plaques	Localized or diffuse	May be asymptomatic
Esophageal papillomatosis	Multiple excrescences	Diffuse	Asymptomatic
Acanthosis nigricans	Tiny nodules	Diffuse	Skin disease
Cowden's disease	Tiny nodules (hamartomatous polyps)	Diffuse	Hereditary disorder with associated malignant tumors of skin, gastrointestinal tract, and thyroid
Leukoplakia	Tiny nodules	Localized or diffuse	Rare

TABLE
28-3

Solitary Mass Lesions

Cause	Radiographic Findings	Distribution	Comments
MUCOSAL LESIONS			
Papilloma	Sessile or slightly lobulated polyp	Variable	Asymptomatic
Adenoma	Sessile or pedunculated polyp	Distal	Arises in Barrett's mucosa
Inflammatory esophagogastric polyp	Polypoid protuberance with contiguous fold arising near cardia	Distal	Associated reflux esophagitis
Adenocarcinoma or squamous cell carcinoma	Plaquelike, sessile, or polypoid lesion	Variable	Small lesions may be early esophageal cancers
Spindle cell carcinoma	Bulky polypoid mass	Variable	Expands lumen without causing obstruction
Primary malignant melanoma	Bulky polypoid mass	Variable	Expands lumen without causing obstruction
SUBMUCOSAL LESIONS			
Leiomyoma	Smooth submucosal mass	Variable	Usually asymptomatic; rarely ulcerated
Fibrovascular polyp	Large pedunculated mass with sausage-shaped appearance	Arises in cervical esophagus but extends distally	May occlude larynx, causing asphyxia and sudden death
Granular cell tumor	Smooth submucosal mass	Usually distal	Associated lesions on skin or tongue
Lipoma	Sessile or pedunculated lesion	Variable	Fat density on computed tomography (CT)
Hemangioma	Smooth submucosal mass	Variable	Risk of exsanguination
Idiopathic varix	Smooth submucosal mass	Variable	Effaced or obliterated with esophageal distention (unless thrombosed)
Duplication cyst	Smooth submucosal mass	Right lateral wall of distal esophagus	Fluid density on CT

TABLE 28-4 Multiple Submucosal Masses

Cause	Distribution	Comments
BENIGN LESIONS		
Leiomyomas	Middle or distal	May be asymptomatic
Granular cell tumors	Middle or distal	Associated lesions on skin or tongue
Hemangioma	Diffuse	Osler-Weber-Rendu disease
Retention cysts (esophagitis cystica)	Distal	Asymptomatic
MALIGNANT LESIONS		
Hematogenous metastases	Middle or distal	Very rare in esophagus
Lymphoma	Diffuse	Usually non-Hodgkin's lymphoma
Leukemia	Diffuse	Usually asymptomatic
Kaposi's sarcoma	Diffuse	Patients with AIDS

TABLE 28-5 Thickened Folds

Cause	Radiographic Findings	Distribution	Comments
Varices	Tortuous or serpiginous folds	Uphill—distal Downhill—middle	Effaced or obliterated with esophageal distention; no dysphagia
Esophagitis	Smooth, nodular, or scalloped folds	Diffuse	Reflux symptoms or other findings of esophagitis
Varicoid carcinoma	Thickened, lobulated folds	Variable	Rigid, fixed appearance at fluoroscopy; dysphagia common
Lymphoma	Thickened, lobulated folds	Variable	Usually non-Hodgkin's lymphoma

TABLE 28-6 Strictures

Cause	Radiographic Findings	Comments
DISTAL ESOPHAGUS		
Peptic strictures	Symmetric or asymmetric; moderate length or ringlike	Associated hiatal hernia
Barrett's esophagus	Symmetric or asymmetric (i.e., peptic strictures)	Barrett's mucosa found in 40% of peptic strictures
Nasogastric intubation	Long area of narrowing	Rapidly progressive
Zollinger-Ellison syndrome	Long area of narrowing	May be initial manifestation of disease; hypergastrinemia
Crohn's disease	Short or long	Advanced Crohn's disease in small bowel or colon
Alkaline reflux strictures	Short or long	Rapidly progressive; seen after partial or total gastrectomy
Carcinoma (usually adenocarcinoma)	Irregular narrowing with nodularity or ulceration	Arises in Barrett's esophagus; often invades gastric cardia and fundus; recent onset of dysphagia and weight loss
UPPER OR MIDESOPHAGUS		
Barrett's esophagus	Tapered or ringlike	Hiatal hernia and/or gastroesophageal reflux; adjacent reticular pattern abutting distal aspect of stricture
Radiation	Usually tapered	History of radiation therapy (>50 Gy)
Eosinophilic esophagitis	Variable narrowing with concentric rings (ringed esophagus)	History of allergies, asthma, and peripheral eosinophilia; predominantly in men
Caustic ingestion	Single or multiple; long strictures common	History of caustic ingestion
Oral medications	Often near level of enlarged left atrium, left main bronchus, or aortic arch	Potassium chloride, quinidine, alendronate, nonsteroidal anti-inflammatory drugs, tetracycline, or doxycycline
Opportunistic infection (usually candidiasis)	Short or long	History of <i>Candida</i> esophagitis
Epidermolysis bullosa dystrophica	High strictures or webs	Skin disease
Benign mucous membrane pemphigoid	High strictures or webs	Skin disease
Chronic graft-versus-host disease	Relatively long	History of bone marrow transplantation
Glutaraldehyde-induced injury	Long and tapered	Rapidly progressive stricture within weeks of endoscopy
Congenital esophageal stenosis	Tapered narrowing with concentric rings	Long-standing dysphagia for solids; food impactions
Carcinoma (usually squamous cell carcinoma)	Irregular narrowing with nodularity or ulceration	History of smoking and/or alcohol consumption; recent onset of dysphagia and weight loss
Metastatic tumor	Tapered or irregular narrowing	Usually lung or breast cancer
SMALL-CALIBER ESOPHAGUS		
Eosinophilic esophagitis	Associated rings common	History of allergies, asthma, and peripheral eosinophilia; predominantly in men
Lichen planus	Sometimes have focal strictures	Skin lesions; predominantly in women
Caustic ingestion	Greater irregularity and narrowing than other causes of small-caliber esophagus	History of caustic ingestion

Differential Diagnosis

Gastric or duodenal ulcers (peptic ulcers) are thought to occur in about 10% of the adult population in the West.¹ Peptic ulcers are important not only because of the frequent occurrence of pain or other symptoms, but also because of the morbidity and mortality associated with complications such as bleeding and perforation. It has been well established that *Helicobacter pylori* and nonsteroidal anti-inflammatory drugs (NSAIDs) have a major role in ulcer development. Duodenal ulcers are almost always benign, but a small percentage of gastric ulcers are found to be malignant, so gastric ulcers require careful evaluation and follow-up to differentiate benign from malignant lesions.

Epidemiology and Pathogenesis

During the early 20th century, gastric ulcers were much more common than duodenal ulcers.² Since that time, there has been a dramatic reversal of this relationship, so duodenal ulcers are now more common than gastric ulcers.² Although duodenal ulcers occur in adults of all ages, gastric ulcers are found

predominantly in patients older than 40 years.^{1,2} Regardless of their site of origin, peptic ulcers have an equal gender distribution.³ Gastric and duodenal ulcers are characterized by seasonal variations, with a higher frequency in spring and autumn and a lower frequency in summer.⁴

A voluminous body of literature has shown convincingly that *H. pylori* and NSAIDs are responsible for the vast majority of gastric ulcers and that *H. pylori* is the causative agent for almost all duodenal ulcers. Nevertheless, *H. pylori*-negative ulcers may occasionally develop in the absence of NSAID use.⁵ Other possible causes of gastric ulcers include steroids, tobacco, alcohol, coffee, stress, duodenogastric reflux of bile, and delayed gastric emptying. Hereditary factors have also been implicated. These subjects are discussed separately in the following sections.

HELICOBACTER PYLORI GASTRITIS

H. pylori is a gram-negative, spiral bacillus that was first isolated on endoscopic biopsy specimens from the stomach by Warren and Marshall in 1983.⁶ Since then, *H. pylori* has been recognized as the major cause of gastric and duodenal ulcers.⁷⁻⁹ In various studies, the prevalence of *H. pylori* gastritis has ranged from 60% to 80% in patients with gastric ulcers and from 95% to 100% in patients with duodenal ulcers.^{7,10,11}

The mechanism whereby *H. pylori* predisposes to the development of ulcers remains uncertain. It has been shown that patients with *H. pylori* gastritis have increased secretion of gastrin, with high basal and peak acid outputs.¹² As a result, a gastrin-mediated increase in gastric acid secretion may be a key factor in the pathogenesis of ulcers. Although most people with *H. pylori* never develop ulcers, more virulent strains of the organism are more likely to be associated with ulcer formation.^{12,13} In particular, a *cagA*-positive strain of *H. pylori* has been implicated in patients with duodenal ulcers and, to a lesser degree, gastric ulcers.¹⁴ Many of these patients also have evidence of gastric metaplasia at the borders of the ulcers, with infection of the metaplastic epithelium by *H. pylori*.^{14,15} The infected mucosa may therefore be more susceptible to ulceration.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

In various studies, the prevalence of gastric ulcers in patients treated with aspirin or other NSAIDs has ranged from 15% to 30%.¹⁶⁻¹⁸ It has been shown that NSAIDs inhibit prostaglandin production by blocking the formation of cyclooxygenase 1 (COX-1), a rate-limiting enzyme for the synthesis of prostaglandins.^{18,19} This phenomenon occurs even with aspirin doses as low as 10 mg daily (compared with a dose of 81 mg daily for cardiovascular prophylaxis).²⁰ Because prostaglandins have cytoprotective properties, inhibition of prostaglandin synthesis can lead to mucosal injury and ulceration.^{18,19,21,22}

The development of gastric ulcers in patients on NSAIDs is also related to a topical effect caused by breakdown of the mucosal barrier.^{19,22} It has been shown that aspirin disrupts the mucus gel layer in the stomach, allowing acid to damage the gastric mucosa, even in the presence of normal or decreased acid secretion.²³ Altered mucosal resistance is therefore thought to be a major factor in ulcer pathogenesis. Nevertheless, it has been shown that patients taking enteric-coated aspirin have the same risk of upper gastrointestinal (GI) bleeding as those taking non-enteric-coated aspirin.²⁴ Ulcers have also been induced in cats by intravenous (IV) infusion of aspirin.²⁵ Thus, the development of ulcers is ultimately mediated by a combination of the topical and systemic effects of NSAIDs.

Chronic NSAID use is associated not only with an increased frequency of ulcers but also an increased frequency of complications such as perforation, obstruction, and bleeding.^{26,27} Studies have shown that people taking NSAIDs have a twofold to sixfold higher risk of developing these complications than those not taking NSAIDs.¹⁸ The risk increases even further in people over 60 years of age.²¹ A careful NSAID history should therefore be obtained in all patients with *H. pylori*-negative ulcers because of the likelihood that these ulcers are NSAID-related.

STEROIDS

Some investigators believe that steroids predispose to the development of ulcers, particularly gastric ulcers. This concern often results in discontinuation of steroids in patients with ulcer symptoms or GI bleeding. In a large study, however, patients receiving steroids were found to have the same frequency of ulcers as the general population.²⁸ It is therefore questionable whether steroids have any role in ulcer pathogenesis. Nevertheless, steroids can mask the clinical findings associated with ulcers, so a large or even perforated ulcer may fail to produce symptoms in these patients.

TOBACCO, ALCOHOL, AND COFFEE

Some investigators have found that cigarette smokers are more likely to have ulcers than nonsmokers^{29,30} and that perforated ulcers are also more likely to occur in these individuals.³¹ Others have found no significant correlation between smoking and ulcers.³² Although alcohol and coffee may stimulate acid secretion, their role in ulcer pathogenesis remains uncertain.²⁹

STRESS

Some investigators believe that emotional stress contributes to the development of peptic ulcers by increasing peptic acid secretion.^{33,34} In one study, extreme emotional stress after a major earthquake in Japan resulted in an increased frequency of gastric ulcers, particularly bleeding ulcers.³⁵ Others have found that stressful life events are no more common in patients with ulcers than in the general population.³⁶ Thus, the role of stress in the development of ulcers remains uncertain.

GASTRODUODENAL REFLUX OF BILE AND DELAYED GASTRIC EMPTYING

Some patients with gastric ulcers have an unusually high concentration of bile acids in the stomach,³⁷ so duodenogastric

reflux of bile has been implicated in ulcer pathogenesis. Gastric stasis from gastric outlet obstruction or gastroparesis may also predispose to the development of gastric ulcers by prolonging exposure of the stomach to its own peptic secretions.³⁸ The latter ulcers have been called Dragstedt ulcers based on the name of the investigator who described them.³⁸

HEREDITARY FACTORS

A small percentage of patients with peptic ulcers have a family history of ulcers.^{39,40} This familial aggregation of ulcers is explained primarily by hereditary rather than environmental factors because studies have found a much greater concordance of ulcers in monozygotic twins than in dizygotic twins.³⁹ Patients with blood type O also have a higher incidence of ulcers than those with other blood types.³⁹ Finally, peptic ulcers are more common in patients with genetic syndromes such as multiple endocrine neoplasia type 1, systemic mastocytosis, and tremor-nystagmus-ulcer syndrome.³⁹ Thus, hereditary factors have clearly been implicated in the development of ulcers.

Clinical Findings

Patients with peptic ulcers often present with localized epigastric pain between the xiphoid cartilage and umbilicus.⁴¹ Ulcer pain tends to have a rhythmic nature; gastric ulcer pain typically occurs less than 2 hours after meals, whereas duodenal ulcer pain occurs 2 to 4 hours after meals and is more likely to wake the patient at night.⁴¹ Nevertheless, there is so much overlap in the timing of the pain that it is difficult to differentiate gastric and duodenal ulcers on clinical grounds.

Some patients with peptic ulcers may have right upper quadrant, back, or chest pain or other symptoms such as bloating, belching, nausea, vomiting, anorexia, and weight loss.⁴¹ Depending on the clinical findings, the differential diagnosis may include reflux esophagitis, gastritis, duodenitis, cholecystitis, irritable bowel syndrome, ischemic bowel disease, Crohn's disease, pancreatitis, and gastric or pancreatic carcinoma.⁴¹

The diagnosis of peptic ulcer disease is complicated by the fact that patients with classic ulcer symptoms are not always found to have ulcers.⁴² Conversely, 25% to 50% of patients with gastric or duodenal ulcers are asymptomatic.^{41,43} These individuals may not seek medical attention until the development of potentially catastrophic complications such as perforation, bleeding, or obstruction. When ulcers on the posterior wall of the stomach or duodenum penetrate into the pancreas, the normally rhythmic epigastric pain associated with ulcers is replaced by a more constant pain that radiates to the back. In contrast, free perforation of a gastric or duodenal ulcer causes peritonitis. The major factors contributing to mortality in patients with perforated peptic ulcers include age older than 60 years and a delay of more than 24 hours from the time of diagnosis to the time of surgery.⁴⁴

Patients with antral, pyloric channel, or duodenal ulcers associated with edema, spasm, or scarring may present with postprandial nausea and vomiting related to gastric outlet obstruction. Other patients with pyloric channel ulcers may develop the so-called pyloric channel syndrome with severe postprandial epigastric pain relieved by vomiting.^{45,46}

Peptic ulcers are the most common cause of acute upper GI bleeding, accounting for about 50% of cases.⁴⁷ Some patients have one or more episodes of massive hemorrhage, manifested

by hematemesis, melena, or rectal bleeding, whereas others have chronic, low-grade bleeding, manifested by guaiac-positive stool or iron-deficiency anemia.⁴¹ Gastric ulcers are more likely to bleed than duodenal ulcers, probably because of the greater size of the ulcer craters and older age of the patients.⁴¹ When ulcers are found in the duodenum, however, postbulbar duodenal ulcers are more likely to be associated with upper GI bleeding (particularly massive bleeding) than those in the duodenal bulb.⁴⁸ Bleeding from ulcers ceases spontaneously in about 80% of cases, but some form of therapy is required to control the bleeding in the remaining 20%.⁴³

Treatment

The treatment for peptic ulcers depends on the underlying cause. If *H. pylori* gastritis is confirmed by endoscopic biopsy specimens or by noninvasive tests such as a urea breath test, serologic test, or stool antigen test (see Chapter 30), there is strong evidence that eradication of *H. pylori* leads to more rapid healing of gastric and duodenal ulcers and a much lower rate of ulcer recurrence.⁴⁹⁻⁵¹ Expert panels convened by the National Institutes of Health and American Digestive Health Foundation therefore concluded that all patients with *H. pylori*-related gastric or duodenal ulcers should receive combination therapy with antimicrobial and antisecretory agents.^{52,53} Various combinations of antibiotics and antisecretory agents (proton pump inhibitors) have been shown to be highly effective in eradicating *H. pylori*.⁵⁴⁻⁵⁶ As a result, these patients can literally be cured of their ulcer disease without need for long-term maintenance therapy with antisecretory agents, unless they become infected by another strain of the organism.

In the absence of *H. pylori*, H₂ receptor antagonists have proved to be highly effective in accelerating healing of gastric and duodenal ulcers by suppressing acid secretion.⁵⁷ Proton pump inhibitors such as omeprazole are even more effective in suppressing acid secretion and accelerating ulcer healing by selectively inhibiting the gastric proton pump that controls the first step in the production of gastric acid.⁵⁸ Because NSAID-related ulcers are associated with decreased synthesis of prostaglandins (see earlier), misoprostol (a synthetic prostaglandin E analogue) has been used to accelerate ulcer healing in these patients.⁵⁹ Prostaglandins and prostaglandin analogues also decrease the risk of developing gastric ulcers in patients on

NSAIDs.⁶⁰ Sucralfate, colloidal bismuth, and carbenoxolone are other drugs that have been used to treat ulcers.

Surgery may be required for recurrent or intractable ulcers that fail to heal with medical therapy, for ulcer complications such as bleeding, obstruction, and perforation, and for ulcers that have equivocal or suspicious findings on barium studies or endoscopy. The most common operations include partial gastrectomy, vagotomy and pyloroplasty, and hyperselective vagotomy. These surgical procedures and their complications are discussed in Chapter 35. Because of better diagnosis and medical treatment of peptic ulcers, the need for surgery in these patients has decreased considerably since the late 1960s.^{61,62}

Radiographic Findings

GASTRIC ULCERS

Examination Technique

The double-contrast examination should be performed as a biphasic study that includes double-contrast views of the stomach with a high-density barium suspension and prone or upright compression views with a low-density barium suspension (see Chapter 17). Ulcer detection is facilitated by IV administration of 0.1 mg of glucagon to induce gastric hypotonia. Ulcers located on the posterior wall or on the lesser or greater curvature of the stomach are usually well seen on routine double-contrast views obtained with the patient in a supine or supine oblique position. Flow technique can be used to better delineate shallow ulcers on the posterior wall by slowly rotating the patient from side to side to manipulate a thin layer of high-density barium over the dependent surface (Fig. 29-1).⁶³ Upright compression views are also helpful for evaluating ulcers on the lesser curvature.⁶⁴

It is important to be aware of the limitations of double-contrast studies for detecting ulcers on the anterior (nondependent) wall of the stomach. Because of the effect of gravity, these ulcers may not fill with barium on double-contrast views with the patient in the usual supine or supine oblique position (Fig. 29-2A). Prone compression views of the gastric antrum and body should therefore be obtained routinely to demonstrate these anterior wall ulcers (Fig. 29-2B). Double-contrast views of the anterior wall can also be obtained by placing the patient in a prone Trendelenburg position.⁶⁵

Figure 29-1 Importance of flow technique for posterior wall ulcers.

A. Supine double-contrast view shows no evidence of an ulcer, even in retrospect. **B.** With flow technique, an ulcer (arrow) is seen on the posterior wall of the antrum. Note how folds radiate to the edge of the ulcer crater. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Shape

Gastric ulcers are typically seen as round or ovoid collections of barium (see Figs. 29-1B and 29-2B). Ulcer craters may have a variety of shapes and configurations, appearing as linear, rod-shaped, rectangular, serpiginous, or flame-shaped lesions (Fig. 29-3).⁶⁶⁻⁶⁹ Linear ulcers constitute about 5% of all gastric ulcers diagnosed on double-contrast studies.⁶⁸ These linear ulcers

probably represent a stage of ulcer healing in the stomach and duodenum.^{68,69}

Size

The radiographic sensitivity in detecting gastric ulcers is related primarily to ulcer size; ulcers larger than 5 mm are more likely to be detected on barium studies.⁷⁰ A major advantage of double-contrast technique is its ability to distend the stomach

Figure 29-2 Importance of prone compression for anterior wall ulcers. **A.** Supine double-contrast view shows abnormal folds in the antrum without a definite ulcer. **B.** Prone compression view shows filling of an anterior wall ulcer (arrow). Note how folds radiate to the edge of the ulcer crater. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 29-3 Gastric ulcers of different shapes.

A. This patient has star-shaped (straight arrow) and linear (curved arrow) ulcers in the antrum. **B.** In another patient, a rod-shaped ulcer (arrow) is seen in the stomach.

Figure 29-4 Small gastric ulcers. **A, B.** Despite their small size, these lesser curvature ulcers (arrows) are well seen on double-contrast radiographs.

Figure 29-5 Giant gastric ulcer. A giant ulcer (arrows) is seen projecting from the lesser curvature of the upper gastric body. Large ulcers tend to be located more proximally in the stomach.

and efface normal folds, enabling visualization of small ulcers (Fig. 29-4). Most gastric ulcers diagnosed on double-contrast studies are smaller than 1 cm.⁶⁹ The high prevalence of small ulcers may also be related to the aggressive medical treatment that these patients often receive before undergoing radiologic investigations.

Large ulcers tend to be located more proximally in the stomach (Fig. 29-5).⁷¹ These ulcers may occasionally be recognized on abdominal radiographs by the presence of gas in the ulcer crater. Giant gastric ulcers (ulcers > 3 cm in size) are

associated with a higher risk of complications such as bleeding and perforation.⁷² However, most giant ulcers are found to be benign.⁷² Thus, the size of the ulcer crater has no relationship to the presence of carcinoma.

Location

Most benign gastric ulcers are located on the lesser curvature or posterior wall of the gastric antrum or body.^{69,71,73,74} In various studies, only 1% to 7% of benign ulcers were found to be located on the anterior wall and 3% to 11% on the greater curvature.^{69,71,73,75} In younger people, ulcers tend to be located in the antrum, whereas in older individuals, they are more likely to be located in the upper body, particularly on the lesser curvature.^{76,77} These high lesser curvature ulcers in older patients have been called *geriatric ulcers*.⁷¹

Benign greater curvature ulcers are almost always located in the distal half of the stomach; the vast majority are caused by ingestion of aspirin or other NSAIDs.^{69,78} Because these ulcers rarely occur on the proximal half of the greater curvature, any ulcers in this location should be considered worrisome for malignant tumor until proved otherwise. Except for these ulcers high on the greater curvature, the location of the ulcer has no relationship to the presence of carcinoma.

Gastric ulcers are occasionally found in hiatal hernias.⁷⁹ They tend to occur on the lesser curvature aspect of the hernia, where the hernia sac is compressed by the adjacent esophageal hiatus of the diaphragm (see Chapter 26).⁷⁴ Because the hernia is inaccessible to palpation, double-contrast technique is particularly helpful for showing these ulcers.

Morphologic Features

Ulcers on the lesser or greater curvature are readily visualized in profile on barium studies, permitting analysis of the size, shape, and depth of the ulcer crater as well as associated findings such as radiating folds, Hampton's line, or an ulcer mound or collar. Ulcers on the anterior or posterior wall may be difficult or impossible to visualize in profile, however, so these lesions must be evaluated on the basis of their appearance en face. In such cases, double-contrast technique is particularly helpful in assessing the surrounding mucosa for signs of benign or malignant disease.

Figure 29-6 Lesser curvature ulcers. **A.** A smooth, round ulcer (arrow) is seen projecting beyond the lesser curvature. The radiating folds and enlarged areas gastricae in the adjacent mucosa are caused by surrounding edema and inflammation. **B.** In another patient, a lesser curvature ulcer (large arrow) is demonstrated on a prone compression view. Note the radiolucent band of edema or ulcer collar (small arrows) adjacent to the ulcer. Both these cases demonstrate classic features of benign gastric ulcers. (A from Levine MS, Creteur V, Kressel HY, et al: *Benign gastric ulcers: Diagnosis and follow-up with double contrast radiography*. *Radiology* 164:9–13, 1987.)

Lesser Curvature Ulcers. Ulcers on the lesser curvature typically appear as smooth, round or ovoid craters that project beyond the contour of the adjacent gastric wall (Fig. 29-6; see Fig. 29-4).^{64,69,80,81} In some patients with lesser curvature ulcers, upright compression views may reveal a thin radiolucent line that separates barium in the ulcer crater from barium in the gastric lumen.^{64,80} This so-called Hampton's line results from undermining of the mucosa surrounding the crater.⁶⁴ In other patients, the rim of undermined mucosa may become more edematous, producing a wide radiolucent band, or ulcer collar (see Fig. 29-6B).⁶⁴ Occasionally, edema and inflammation surrounding the ulcer produces an ulcer mound, seen in profile as a smooth, bilobed, hemispheric mass projecting into the lumen on both sides of the ulcer.⁶⁴ Ulcer mounds usually have poorly defined outer borders that form obtuse, gently sloping angles with the adjacent gastric wall.⁶⁴ Hampton's lines and ulcer mounds and collars are considered to be classic features of benign gastric ulcers, but these findings are present in only a small percentage of all patients with lesser curvature ulcers.

Retraction of the gastric wall adjacent to lesser curvature ulcers sometimes leads to the development of smooth, symmetric folds that radiate directly to the edge of the ulcer crater (see Fig. 29-6A).⁶⁹ Occasionally, these ulcers may be associated with retraction of the opposite wall, producing an incisura on the greater curvature. Other lesser curvature ulcers may be associated with focal enlargement of areas gastricae surrounding the ulcer because of edema and inflammation of the adjoining mucosa (see Fig. 29-6A).⁶⁹

Greater Curvature Ulcers. In the past, almost all ulcers on the greater curvature of the stomach were thought to be malignant.⁸² It is now recognized, however, that benign ulcers do occur on the distal half of the greater curvature in patients who are taking aspirin or other NSAIDs (Figs. 29-7 and 29-8).^{69,78} The location of these ulcers on the greater curvature is presumably related to the effect of gravity because the dissolving aspirin tablets collect in the most dependent portion of the stomach, causing localized mucosal injury. Such lesions have been called *sump ulcers* because of their typical location on the greater curvature.⁷⁸ A similar phenomenon may also account for the frequent finding of linear or serpiginous erosions in the body of the stomach, on or near the greater curvature in patients who are taking NSAIDs (see Chapter 30).⁸³ Because of their location, greater curvature ulcers have a tendency to penetrate inferiorly into the gastrocolic ligament, occasionally leading to the development of a gastrocolic fistula (see later, "Fistulas").

In contrast to ulcers on the lesser curvature, greater curvature ulcers may appear to have an intraluminal location because of circular muscle spasm and retraction of the adjacent gastric wall (see Fig. 29-8A).⁸⁴ Greater curvature ulcers may also be associated with considerable surrounding mass effect and thickened, irregular folds secondary to marked edema and inflammation accompanying the ulcers (see Fig. 29-8).^{69,84} Because of these morphologic features, benign greater curvature ulcers often have a suspicious radiographic appearance, so the usual radiographic criteria for differentiating benign and malignant ulcers elsewhere in the stomach are unreliable for ulcers in this location.^{69,84} Endoscopy and biopsy may therefore be required

Figure 29-7 Greater curvature ulcers caused by aspirin and indomethacin. **A.** A small aspirin-induced ulcer (black arrow) is seen in the gastric body abutting the greater curvature. An area of scarring is also seen more distally on the greater curvature (white arrow) secondary to scarring from a previous ulcer in this location. **B.** In another patient, an extremely shallow indomethacin-induced ulcer (arrow) is seen on the greater curvature. Radiating folds and other signs of ulcer disease are absent. This ulcer could easily be missed without optimal technique. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 29-8 Giant greater curvature ulcers caused by aspirin. **A.** This large ulcer (arrows) on the greater curvature has an apparent intraluminal location and is associated with thickened, irregular folds and considerable mass effect from a surrounding mound of edema. **B.** In another patient, thickened, irregular folds are seen abutting a large greater curvature ulcer (arrows). In both cases, endoscopic biopsy specimens revealed no evidence of tumor, and follow-up studies after treatment with antisecretory agents showed complete healing of the ulcers. Both patients had been on high doses of aspirin. (A from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

for some greater curvature ulcers, despite a history of aspirin ingestion.

Posterior Wall Ulcers. Ulcers on the posterior (dependent) wall of the gastric antrum or body may fill with barium on routine double-contrast views, producing the conventional appearance of an ulcer crater (Fig. 29-9; see Fig. 29-1B). However, shallow ulcers on the posterior wall may appear as ring shadows on these views because of a thin layer of barium coating the rim of the unfilled crater (Fig. 29-10A). In such cases, flow technique can be used to manipulate the barium pool over the surface of the ulcer and demonstrate filling of the ulcer crater (Fig. 29-10B).⁶³ It is important not only to determine the size and shape of these posterior wall ulcers, but also to assess the appearance of the adjoining mucosa. Not infrequently, the areae gastricae are enlarged or distorted in the region of the ulcer because of surrounding edema and inflammation.⁶⁹ An ulcer collar or mound can sometimes be seen en face as a radiolucent halo of edematous tissue with poorly

defined outer borders that fade peripherally into the adjacent mucosa. Posterior wall ulcers may also be associated with a spectacular collection of folds that radiate directly to the edge of the ulcer crater.⁶⁹ Occasionally, the edema and spasm associated with antral ulcers may cause such severe narrowing and deformity of the distal stomach that it is difficult to evaluate these ulcers by the usual radiologic criteria (Fig. 29-11).

Anterior Wall Ulcers. Ulcers on the anterior (nondependent) wall of the gastric antrum or body may also appear as ring shadows on routine double-contrast views because of barium coating the rim of the unfilled ulcer crater tangential to the central beam of the x-ray (Fig. 29-12A).^{81,85} In such cases, the ulcer may be shown by turning the patient 180 degrees into the prone position, so the ulcer is located on the dependent wall and fills with barium (Fig. 29-12B). Prone compression views of the stomach with low-density barium should therefore be obtained routinely to demonstrate these anterior wall ulcers.

Multiplicity

With double-contrast technique, multiple ulcers have been detected in about 20% of patients with ulcers or ulcer scars,⁸⁶ a figure approximating the 20% to 30% prevalence of multiple ulcers at endoscopy, surgery, and autopsy.⁸⁷ The presence of multiple ulcers is often thought to favor benign disease. In one study, however, 20% of patients with multiple gastric ulcers had malignant lesions.⁸⁸ It is now recognized that patients may have coexisting benign and malignant ulcers, so each ulcer must be evaluated individually on barium studies.

Figure 29-9 Posterior wall ulcer. A large ulcer (arrow) is present on the posterior wall of the stomach. Multiple folds are seen radiating to the edge of the ulcer crater. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 29-10 Ring shadows caused by shallow posterior wall ulcers. **A.** Supine double-contrast view shows two discrete ring shadows (arrows) in the upper body of the stomach secondary to barium coating the rim of shallow, unfilled ulcers on the posterior wall. **B.** The use of flow technique to manipulate the barium pool over the surface of the ulcers results in filling of the ulcer craters (arrows).

When multiple gastric ulcers are present, they tend to be located in the gastric antrum or body (see Fig. 29-3A). Multiple gastric ulcers are more likely to develop in patients who are taking aspirin or other NSAIDs (see Fig. 29-7A). In one study, 80% of patients with multiple ulcers had a history of aspirin use.⁸⁷ A careful drug history should therefore be obtained from these patients.

Ulcer Healing and Scarring

The radiologic assessment of ulcer healing is important for evaluating the success or failure of medical therapy and for

Figure 29-11 Antral ulcer associated with marked edema and spasm. A large ulcer (arrow) is seen in the gastric antrum. This ulcer is difficult to evaluate by the usual radiologic criteria because of antral narrowing and deformity secondary to marked edema and spasm accompanying the ulcer.

Figure 29-12 Partial ring shadow caused by an anterior wall ulcer. **A.** Supine double-contrast view shows a partial ring shadow (arrow) in the antrum. **B.** Prone compression view shows the anterior wall ulcer (arrow) filling with barium. (From Levine MS, Rubesin SE, Herlinger H, et al: *Double contrast upper gastrointestinal examination: Technique and interpretation*. Radiology 168:593–602, 1988.)

Figure 29-13 Development of a linear ulcer during healing. **A.** A large, round ulcer (arrowhead) is seen on the posterior wall of the antrum. **B.** Follow-up study 8 weeks later shows substantial ulcer healing with a residual linear ulcer (arrow) in this location. (From Levine MS, Creteur V, Kressel HY, et al: *Benign gastric ulcers: Diagnosis and follow-up with double-contrast radiography*. Radiology 164:9–13, 1987.)

confirming the presence of benign ulcer disease (see later, “Benign Versus Malignant Ulcers”). Ulcer healing may be manifested on barium studies not only by a decrease in the size of the ulcer crater but also by a change in its shape. Previously round or ovoid ulcers often have a linear appearance on follow-up studies, so linear ulcers presumably represent a stage of ulcer healing (Fig. 29-13).^{68,69} Other ulcers may undergo splitting, so the ulcer crater is replaced by two separate niches at the periphery of the original ulcer (Fig. 29-14).⁶⁹ This phenomenon most likely occurs because healing and re-epithelialization are more rapid in the central portion of the ulcer than in the periphery.

Benign gastric ulcers usually have a marked response to treatment with antisecretory agents. The average interval between the initial barium study showing the ulcer and the follow-up study showing complete healing is about 8 weeks.⁶⁹

Follow-up studies to demonstrate ulcer healing should therefore be performed after 6 to 8 weeks of medical treatment because studies performed sooner are unlikely to show complete healing.

In general, complete radiologic healing of a gastric ulcer has been considered a reliable sign that the ulcer is benign. Rarely, complete healing of malignant ulcers may occur with medical therapy.^{89,90} However, nodularity of the ulcer scar or irregularity, clubbing, or amputation of radiating folds should suggest the possibility of an underlying malignant tumor. The surrounding gastric mucosa must therefore be evaluated carefully after ulcer healing has occurred. If suspicious findings are present, endoscopy and biopsy are still required to rule out a malignant lesion.

Ulcer healing may lead to the development of ulcer scars, which are visible on double-contrast studies in 90% of patients with healed gastric ulcers.⁶⁹ These scars are usually manifested

Figure 29-14 Splitting of an ulcer during healing. **A.** A round ulcer (arrow) is seen adjacent to the lesser curvature. **B.** Follow-up study several weeks later shows splitting of the ulcer with two closely spaced niches (arrowheads) at the site of the original crater.

Figure 29-15 Healing of a lesser curvature ulcer with scarring. **A.** A small, benign-appearing ulcer (arrowhead) is seen on the lesser curvature. **B.** Follow-up study 5 months later shows complete healing of the ulcer with slight flattening and retraction of the adjacent gastric wall (arrowhead). (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

by a central pit or depression, radiating folds, and/or retraction of the adjacent gastric wall.^{69,91,92} The location of the ulcer is a major determinant of the morphologic features of the scar. Healing of ulcers on the lesser curvature is often associated with the development of relatively innocuous scars, manifested by slight flattening or retraction of the adjacent gastric wall (Fig. 29-15).^{69,91} In contrast, healing of ulcers on the greater curvature or posterior wall is sometimes associated with the development of a spectacular collection of radiating folds (Fig. 29-16).^{69,81,91} The folds may converge to a central point or to a circular or linear pit or depression (Fig. 29-17).^{69,91,92} This central depression can be mistaken radiographically for a shallow, residual ulcer crater. However, the central depression of an ulcer scar tends to have more gradually sloping margins than an ulcer crater and should remain unchanged on sequential follow-up studies. A re-epithelialized ulcer scar can

also be differentiated from an active ulcer by the presence of normal *areae gastricae* within the central portion of the scar (Fig. 29-18).⁶⁹

Healing of antral ulcers may also lead to the development of a prominent transverse fold that can be mistaken for an antral web or diaphragm.⁹¹ In other patients, severe scar formation may be manifested by antral narrowing and deformity (Fig. 29-19A). The narrowed segment usually has a smooth, tapered appearance, but asymmetric scarring may result in flattening and shortening of the lesser or greater curvature, so the pylorus has an eccentric location in relation to the antrum and duodenal bulb (Fig. 29-19B). Occasionally, an ulcer scar may be associated with such irregular antral narrowing that it mimics the linitis plastica appearance of a primary scirrhous carcinoma of the stomach.⁹³ When antral scarring cannot be differentiated from a scirrhous carcinoma on radiologic criteria, endoscopy

Figure 29-16 Healing of a posterior wall ulcer with scarring. **A.** There is a large posterior wall ulcer with multiple folds radiating to the edge of the ulcer crater. **B.** Follow-up study 8 weeks later shows complete healing of the ulcer with a spectacular collection of folds radiating to the site of the previous crater. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 29-17 Ulcer scar with folds radiating to a central depression. Multiple folds are seen radiating to a central area (arrow) that could be mistaken for a shallow, residual ulcer crater. (From Levine MS, Creteur V, Kressel HY, et al: *Benign gastric ulcers: Diagnosis and follow-up with double-contrast radiography*. *Radiology* 164:9–13, 1987.)

and biopsy are required for a more definitive diagnosis. Healing of ulcers on the lesser curvature of the gastric body may also lead to marked retraction and deformity of the opposite wall, producing a deep incisura on the greater curvature.^{91,92} Rarely, scarring of the gastric body may result in the development of a so-called hourglass stomach with marked circumferential narrowing of the gastric body (Fig. 29-19C).

Benign Versus Malignant Ulcers

More than 95% of gastric ulcers diagnosed in the United States are found to be benign.^{64,94} Nevertheless, radiologic examinations are often thought to be unreliable in differentiating benign ulcers from ulcerated carcinomas. Early reports indicated that 6% to 16% of gastric ulcers that appeared benign on conventional single-contrast barium studies were malignant.⁹⁵⁻⁹⁸

Figure 29-18 Re-epithelialized ulcer scar with centrally radiating folds. This scar can be differentiated from an active ulcer by the presence of normal areae gastricae within the central portion of the scar (arrow). (From Levine MS, Rubesin SE, Herlinger H, et al: *Double contrast upper gastrointestinal examination: Technique and interpretation*. *Radiology* 168:593–602, 1988.)

Although these studies were performed between 1955 and 1975, many gastroenterologists have used these data as the justification for performing endoscopy and biopsy on all patients with radiographically diagnosed gastric ulcers to rule out gastric carcinoma.

With double-contrast techniques, it is possible to obtain a far more detailed study of the mucosa surrounding the ulcer for signs of malignancy, such as irregular mass effect, nodularity,

Figure 29-19 Various types of gastric scarring from ulcer disease. **A.** This patient has tapered narrowing and deformity of the antrum (arrow) caused by scarring from a previous antral ulcer. This degree of narrowing can lead to gastric outlet obstruction. **B.** Another patient has a widened, eccentric pylorus (arrow) caused by asymmetric scarring from peptic ulcer disease. **C.** A third patient has an hourglass stomach with focal narrowing of the gastric body (arrow) from severe ulcer scarring.
